ORIGINAL COMMUNICATIONS.

ON THE PHYSICAL EXAMINATION OF THE ABDOMEN, IN HEALTH AND DISEASE.

By CHARLES J. B. WILLIAMS, M.D., F.R.S.

Although practitioners have long (even before the examination of the chest became a study) been in the habit of proving the condition of the state of the abdominal viscera by means of inspection and palpation, yet it does not appear that any systematic attempt has been made to reduce this mode of investigation to *fixed principles*, which, by rendering it more rational and intelligible, would facilitate and extend its application in practice. The signal aid which the diagnosis of thoracic diseases has derived from the light of physical science, is a sufficient encouragement to attempt the elucidation of abdominal diseases in the same rational point of view. If it be objected, that the signs of the state of the abdomen, being derived chiefly from the touch, are rather to be learnt by experience than taught by precept, it may be answered, that although experience is absolutely necessary for proficiency in all matters in which the senses are concerned, yet a proper analysis of the objects of examination will render this experience much more intelligible and instructive. And this applies as much to the sense of touch as to those of vision and hearing. The *tactus expertus*, a fine delicacy of touch, capable of very nicely feeling and discriminating between impressions, may be more or less acquired by mere experience: but the *tactus eruditus*, the faculty of properly interpreting these impressions, and their differences, includes an exercise of the understanding, and requires a due consideration of the subject in its relations of cause and effect.

In the following papers, I propose to give an outline of the principles of the Physical Examination of the Abdomen, illustrated by facts, which have been supplied by clinical observation. The subject might be extended almost indefinitely in the way of example and further application of the principle; but such prolonged details would be neither con-

sistent with the form and plan of this essay, nor, according to my experience in teaching, calculated to facilitate the task of the learner.

EXAMINATION OF THE ABDOMEN BY INSPECTION.

The shape of the abdomen is determined by the conjoint influence of the walls and of the viscera contained within them. When these are in a healthy state and normal proportions, the shape of the abdomen in front is flat-convex, with slight rounded projections, which give a general rotundity to that region. With slight exceptions, presently to be noticed, the two sides of the abdomen are symmetrical; for, although the contents may differ, the walls, in health, have sufficient weight and tonicity to smooth down the inequalities of the contents. But where wasting or relaxation has rendered the walls very thin or flaccid, as in the aged and emaciated, the contour of the viscera may often be seen through the walls, and the want of symmetry becomes obvious. We may then sometimes trace the position of the viscera with great precision; and in such cases I have repeatedly seen not only the form of the superficial intestines, but their peristaltic motions also, and the changing prominences and depressions which these motions produce.[1] Such cases are instructive, in showing the varied position of the intestines during life, more accurately than the inspection of bodies after death can do.

Such inequalities and motions, however, are rounded off and intercepted by the abdominal walls in their ordinary state of thickness and tension; and the exterior of the abdomen generally indicates the symmetry of *animal life*. Yet, even through this equalizing surface, a correct eye can generally discern certain projections, constituting the exceptions before alluded to, representing the irregularity of parts, which are the seat of the *organic life* of Bichat. The first of these is at the lower four or five ribs on the right side, which bulge outwards a little more than those on the left, and give a rounder shape to the abdominal portion of this side of the chest. It need scarcely be mentioned, that this is due to the liver; whose weight and bulk infringe visibly on the statuary outline of the exterior. Another intruder on the outward symmetry of the abdomen is the stomach; which very commonly makes known its presence and swelling importance, by a prominence to the left of the epigastrium, including the cartilages of the lower left ribs. In persons who have suffered much from dyspepsia, these cartilages are often so prominent as to attract the notice of the patient; being permanently protruded by the habitual distension of the stomach with air; and this deviation from symmetry remains, although the cause may no longer exist. A slight prominence is frequently perceptible in the right iliac region, and at or below the umbilicus, from an accumulation of air in the cœcum and small intestines respectively.

As these inequalities are most conspicuous when the abdominal walls are thinnest and most flaccid, so they are least perceptible, and may disappear altogether, where the walls are thick or tense. The shape of the abdomen is then more perfectly uniform; but it will yet vary,

[1] On several occasions, I have pointed out this phenomenon to the students; and have further shown them, that this contraction of the intestines could be induced at any given spot by smart immediate percussion.

according to whether muscle or fat predominates in the walls; the former making it more flat, with the symmetrical prominences of the muscles and their divisions; the former giving it a smooth rotundity, with a greater convexity around the umbilical depression, where the layer of fat attains its greatest thickness.

After this brief sketch of the normal shape of the abdomen, and its varieties, we may proceed to notice such alterations, caused by disease, as may be available as signs. In order to inspect the abdomen well with this object, the patient should lie flat on the back, with the arms and legs straight, but relaxed, and resting on the bed. For some purposes, a sitting or standing posture may be preferred. In all cases, the observer should place himself so as to survey both halves of the abdomen at a glance; and for this purpose, standing at the foot or head of the bed, or at a sufficient height on either side, is better than a too close inspection. Of course, all covering should be removed from the abdomen, and a good light fall upon it.

Visible Signs of Disease in the Abdomen. Fæculent accumulation in the intestines usually causes a distension of the colon, which is manifest by more or less irregular prominence in the right iliac, and both hypochondriac, and left iliac regions; and if the small intestines are not also much inflated, the abdomen, although enlarged, has a flattened and irregular surface. Even when the small intestines are distended, there is rarely uniformity in the distension; and if the walls of the abdomen are thin or flaccid, the varying shapes of the most inflated bowels may often be distinctly discerned. The same remark applies to colic; in which, although the inflation may be excessive, and the tension of the abdominal muscles more or less constant on account of the pain, yet the spasmodic contraction of portions of the bowel causes inequalities and hollows in parts, visible to the eye, as they are also palpable to the touch, during the knotty twistings of the colicky spasm. In the meteorismus, or tympanitic enlargement of the abdomen in low fever, and in fatal prostration, the case is different. The distension of the intestines is uniform, wholly unresisted by peristaltic contraction, which is suspended, and the tonicity or elasticity of the abdominal walls is sufficient to give an evenness to the flatulent tumour, which is not observed where the intestines partially retain their tone. But even this uniform tympanitic distension (besides the differences to the touch, and to the ear) has a visible distinction in its more globular, or convex projection anteriorly, without the gravitating projections at the flanks or groins, which distinguish a similar degree of distension in ascites.

The chief visible characteristic of ascites, or liquid in the peritoneum, is the smooth roundness of the swelling which it occasions. When the quantity of effusion is small, this may be perceptible only in the most dependent parts; as in the flanks in the supine, and in the hypogastric and inguinal regions in the erect or sitting posture; and the contrast which the smooth fulness of these regions presents to those above, where intestinal and visceral inequalities are more than usually conspicuous, has often attracted my attention in incipient effusion, and led to the conclusive tests of palpation and percussion. When the fluid increases, so as to occupy the whole front of the abdomen, the smooth

rotundity of the enlargement becomes a further evidence of the uniformity of fluid pressure, which, obliterating the umbilicus, gradually expands the abdominal cavity into a large, smooth, and almost polished globe. But the weight of the liquid is also evident, and reveals its nature in the predominant fulness of the lowest parts; and, where the walls of the abdomen are not tense, in the comparative flatness, or less prominent convexity, of the part which lies uppermost. If, however, the walls be put much on the stretch, or there be much gas in the intestines, these are floated upwards, and give more or less prominence, which may remove the flattening proper to the liquid.

In the rare case of effusion of air into the sac of the peritoneum, the surface of the abdomen would be smooth and rounded as in ascites, but more convex anteriorly, and without the ponderating bulge at the lowest parts.

Enlargement of the solid viscera of the abdomen, if considerable, rarely fails to cause some change in the shape of the abdomen, both by their own protrusion, and by their causing an unsymmetrical displacement of the other viscera. A much enlarged liver makes the lower right ribs to bulge outwards, both at the side, in front, and sometimes behind. When the mass extends much below the ribs, it often gives an unusual breadth and prominence to the upper part of the abdomen; and yet this prominence is flatter and smoother than that arising from intestinal distension, which may often be seen below the site of the enlarged liver: change of posture does not materially alter the appearance. Enlargement of the spleen may cause a projection of the lower left ribs at the side in the left hypochondriac region. When extensive, it occupies the whole iliac region, and may reach to the umbilicus and pubis. When the left half of the abdomen is thus filled with the tumour, its smoothness and immobility form a visible contrast with the right side of the abdomen, which is distended by the rounded inequalities of the intestines, and is more affected by the respiratory movements. Change of posture may visibly affect the position of a much enlarged spleen: I have known it to form a visible projection when the patient lay on his face or leaned much forwards. It is very rarely that the kidneys become sufficiently enlarged to affect the shape of the abdomen in front; but I have more than once found a kidney dilated by pyelitis (commonly called abscess) to produce a visible fulness in the lumbar region of that side.

The peculiarities of the enlargement of the abdomen by the gravid uterus have occupied much attention, and form a subject too extensive to be introduced here. Suffice it to say, that although there are considerable varieties in different women, and in the same women in different pregnancies, owing to the condition of the abdominal walls, the quantity of liquor amnii, the mode in which the intestines are displaced, and other circumstances, yet pregnancy beyond the half term pretty constantly forms a visible tumour *above the pubis*, rising more or less high in the abdomen: but whatever the posture and whatever the stage, and whether the distension in the upper part of the abdomen be more or less, there is always a peculiar fulness in the hypogastric region which serves to trace the tumour to the pelvis. In this respect, pregnancy resembles ovarian tumours; and these frequently cannot by their visible

signs be distinguished from it. For although an enlarged ovarium generally occupies the side where it has originated, more prominently than the other, yet when it has attained a large size, it extends over the whole front of the inferior abdomen, and may not project more on one side than the gravid uterus often does. The diagnosis is rather to be sought in palpation, auscultation, and other symptoms. But all these tumours connected with the pelvis are generally visibly discernible from other causes of abdominal enlargement, by their more circumscribed shape, often presenting a terminal projection or outline upwards or at the sides, where the inequalities of the displaced intestines come into view, and vary at different times and in different postures; whilst the mass of the tumour remains little altered, and extends its unbroken continuity to the pubis, with which it is always in close apposition. The distended urinary bladder may form a tumour above the pubis, reaching to the umbilicus, or even higher: it is also to be distinguished by its well-defined upward limit; and its globular or pyriform shape rising from the middle of the pubis, often visibly characterizes it; but conclusive signs are to be found in palpation and percussion.

Tuberculous disease of the mesenteric glands is accompanied by enlargement of the whole abdomen, but the surface is formed by the intestines more than usually distended with air, and pushed by the nodulated masses underneath, forwards in contact with the walls of the abdomen, on which they impress the outlines of their convolutions: the abdominal walls, although tense, are generally so thin as to render their form visible. In my experience, it is very rare for the tuberculous glands to project so far as to reach the surface. On the contrary, in tuberculous deposits on the peritoneum, the result of chronic peritonitis, the solid masses are on the surface, and often form projections or inequalities, visible either at rest, or when the respiratory movements extend to the abdomen.

Malignant disease, when deep-seated, and to a limited extent, only affects the shape of the abdomen in the case of stricture of the alimentary canal; and then, by preventing or increasing its distension with gaseous and other matter. With malignant disease of the œsophagus precluding the deglutition of food, I have known the abdomen so collapsed as to appear absolutely empty, and the aorta could be seen pulsating on the projecting spine. With scirrhous pylorus, I have noticed in some instances a collapse of the lower half of the abdomen, whilst the epigastrium and left hypochondrium have been prominent from the enlarged stomach. In other instances, no such appearance has existed. In stricture of the rectum, colon, or ilio-cæcal aperture, it often happens that the portion of intestine above the obstruction becomes enormously distended, causing a visible prominence in the abdomen: and this may extend so far as to totally derange the ordinary position of the viscera. Malignant tumours connected with the liver, stomach, pancreas, colon, and bladder, may reach so near the surface as to form a visible projection of the walls of the abdomen, and by its shape and position it may give some intimation of its nature.

To conclude, it may be inferred from the preceding illustrations, that the visible signs of disease of the abdomen are constituted by such deviations from its outward form, size, and symmetry, as are obvious to

the eyes; and these become instructive in proportion as they may be referred to known morbid conditions, of the internal organs. In most instances they are not in themselves conclusive, but they are especially valuable in arresting attention at first sight, and in guiding the practitioner to the employment of the senses of touch and hearing, which may give him a more intimate acquaintance with the condition of the internal parts.

(To be continued.)

[*This paper will be continued in the succeeding numbers. We take this opportunity to contradict a report which has been current, that Dr. Williams is connected with this Journal. Except as a contributor of the articles to which his name is attached, Dr. Williams neither has nor ever had any share or cognizance in its composition.* EDITORS.]

ON THE SUBCUTANEOUS BURSÆ: THEIR ANATOMY, PATHOLOGY, AND TREATMENT.

By WILLIAM COULSON, Esq., F.R.C.S.E., Surgeon to the Magdalen, and Consulting Surgeon to the German, Hospitals.

[*Read before the Medical Society of London, November* 23, 1850.]

It has been remarked, that the anatomy of the lymphatic system was discovered by fragments, the thoracic duct by one observer, the lacteals by another, and the common absorbents by a third; nor was it till after the lapse of ages from the discovery of the first fragment, that a Mascagni appeared, who gave to the disjointed parts the character of unity and of system. The same remark applies to the organs of which I propose to speak.

To Winslow and Albinus may be traced the first notice of certain shut sacs, to which the name of Bursæ Mucosæ has been given, situated beneath certain muscles, or between the tendons and the bones, or between tendons; communicating occasionally with important joints, and formed of a membrane analogous to, if not identical with, the synovial sacs or membranes of the joints. After a time, these Bursæ attracted more notice, and began to be viewed as a distinct system. The second Monro described many not previously observed, and Sömmering followed, who discovered and described many more. The inaugural dissertation of Kosch appeared in 1782; in which he clearly points out the deep Bursæ, shewing that they are sometimes absent, sometimes small, and sometimes double, with bilocular cavities, which might or might not communicate; but, from confounding the deep and superficial systems, his observations are deficient in that order which alone can form the basis of future correct and profitable research. He was also aware of the existence of many of the Subcutaneous Bursæ; but he knew them not as a system, which they really are; he considered them as composed of cellular tissue, and essentially of the same structure as the vaginal Bursæ, and those of tendons and muscles; and he happily remarks, that these superficial Bursæ are not wholly foreign to the subject which he discussed; thus intimating a suspicion of a difference existing, which he did not then clearly comprehend. He knew the patellar and anconal Bursæ, and those

over the distal extremities of the metacarpal bones. In addition to these, which I shall call the system of the deep Bursæ, another system has, of late years, been described, called Subcutaneous Bursæ. It is the history of this system which forms the subject of this memoir.

History. Beclard, in his *Additions à l'Anatomie Générale par Bichat*, published in 1821, makes mention of some of these Bursæ, calling them subcutaneous; but he does not seem to regard them as a system; on the contrary, he constantly confounds them with the deeper Bursæ. At last, in 1825, Schreger published his excellent monograph, *De Bursis Subcutaneis*, in which he unfolds the nature, extent, and situation of these organs, and insists on their being received as one system, distinct from all others. Until this view be clearly comprehended, the pathology of these organs must ever remain obscure, and the treatment of their diseased conditions imperfect.

These Subcutaneous Bursæ are situated in various parts of the body, immediately beneath the integuments, of which they are an appendage. They are connected with, and belong to, the subcutaneous cellular adipose membrane, being in no instance continuous with the deep Bursæ, or with the tendons, muscles, or bones, which they protect. The structures composing them are, first, the capsule itself; secondly, certain filaments traversing it; thirdly, folds, or septa, being reduplications of the inner membrane, and these may be either partial or complete; and fourthly, small adipose corpuscular fringes. There is, also, the peculiar fluid secreted by the interior of the sac. In respect of their being shut sacs, intended to facilitate motion and to protect opposing surfaces, and as regards also the fluid they secrete, these Bursæ have analogies, no doubt, with the deeper Bursæ. In the more perfect synovial capsule of the knee-joint, for example, we not only find a shut sac, but septa forming the alar ligaments; being clearly analogous to the septa of the Subcutaneous Bursæ. Nor does the analogy stop here, seeing that we find the alar ligament so fully developed in some animals, as to divide the knee-joint into two cavities—thus converting it from an unilocular into a bilocular sac: this happens in many of the superficial Bursæ. The Subcutaneous Bursæ vary somewhat in form, and even, perhaps, a little in their structure. In the axilla, for example, where they have, probably, the simplest form, they resemble the cells of a bee-hive piled on each other. In the order of simplicity of structure, those of the groin follow. The mode of formation of these Bursæ in the fœtal state illustrates, I think, their varieties in the adult. For we find, sometimes, that the cellular tissue, in no way modified, takes the place of a properly developed Bursa; and this is exactly what happens up to the fifth month of fœtal life. At other times, in the adult, we find them small, but perfect; shewing that their development has been arrested. Even the anconal Bursa, viewed by Schreger as the most perfect, has been found, by other anatomists, small, contracted, or scarcely perceptible. Pathological changes also, by altering the condition of these Bursæ, reduce them to the tissue, out of which they were formed. Sometimes the interior is filled with a serous fluid, and the walls of the sac are thin, and almost pellucid; at other times they become soft, flaccid, porous, and reticulated, and lose their cohesion,—clearly indicating a retrogression to their primitive condition.

The fluid secreted by, and contained within, these Subcutaneous Bursæ, is held by chemists to be an aqueous solution of albumen, combined with saline matters. The epithelium, common to all true articular synovial membranes, cannot be discovered, even with the aid of the microscope, in the lining membrane of these Bursæ.[1]

It would seem that, prior to the second month of fœtal life, these Bursæ are open. A remark applicable to the entire system I now describe, is, that in youth the capsule is thin and pellucid; as age advances, the Bursæ become opaque and yellowish. Blood-vessels abound on the exterior of the sac. The inner surface of the dermoid segment resembles a serous membrane; the opposing surface, on the contrary, has a synovial appearance; that is, it is soft, pulpy, and as if covered with glistening elevations. But if these two surfaces differ, as has been alleged by Schreger, their secretions may also differ, giving a more complex character to the fluid than was at first supposed.

The Subcutaneous Bursa with which surgeons are most familiar, is the one situated over the patella. This Bursa, which may be called the patellar, is of a globular, or rather oval shape, the base being usually limited by the extent of the bone. The walls of the sac, in contact in the healthy state, are bedewed by a fluid analogous to what we find in the ordinary cellular tissue of the body, performing, no doubt, the function of synovia; like that fluid, as has been already mentioned, it is an aqueous solution of albumen, combined with saline matters.

The patellar Bursa belongs essentially to the superficial or subcutaneous system: it is exterior to the crural aponeurosis; and microscopic research, so much improved and extended of late years, merely confirms the accurate conceptions of Schreger. The epithelium investing the inner surface of the articular synovial membranes, is not found in the interior of this or of any other Bursa. The peculiar glistening fibres already described are found to stretch across at various points, forming septa or partitions, more or less complete. In many persons, two Bursæ, and even three, have been observed developed over one patella, perfectly distinct from each other. This duplification or triplification of the Bursæ is not confined to the patellar Bursæ, but extends as well to others. My friend Mr. Ireland brought me, some time ago, a patient with a Bursa of the size of a marble, situated over the right os magnum, which the patient wished to have removed. I dissected it entire, so that it rolled on the table: in three or four months afterwards, another Bursa, as large as the one which had been previously removed, made its appearance in the same situation. Thus may be traced to an imperfect knowledge of the anatomy of these organs, the theory of accidental Bursæ. When a second Bursa appears after the removal of the first, it is simply the enlargement of a second, coeval with the first, and observed then only for the first time by the surgeon.

In the popliteal space, we usually find three Subcutaneous Bursæ,—an external, internal, and middle. The history of these is curious:

[1] Mr. Toynbee examined for me some fresh fluid, which I removed from a carpal bursa. He says: "The gelatinous matter from the bursa consists of a transparent, viscid, semi-fluid substance, interpersed through which are rounded and ovoid cells, containing granular matter, and having one or two transparent nuclei attached to their inner surface."

with similar relations to all the others, they yet present, when enlarged, certain peculiarities. Both surfaces against which the enlarged Bursa presses being comparatively soft and yielding, the swelling does not assume the distinct globular form which those situated over bones exhibit. A case of this kind came under my notice a few months ago. A young woman, æt. 32, applied to me in July last, with a swelling in the right popliteal space, situated principally in the centre of the ham, and of the size of an orange, though more compressed. It was moveable, free from any pulsatory movement, and, when firmly pressed, gave an elastic feel to the fingers. The integuments were very little changed in colour, and the swelling was free from pain. I entertained no doubt of its nature, and punctured it by means of a grooved needle, when an ounce and a half of a white gelatinous fluid, much resembling the vitreous humour, escaped; a compress was applied over the part, strips of soap plaster over this, and a bandage tightly over the whole. On removing the pressure at the end of a week, a re-accumulation of the fluid had taken place. The swelling was again punctured, and the fluid, which was much less than on the previous occasion, allowed to escape. The pressure was applied in the same way as before, and removed from time to time. No fresh accumulation took place, and at the end of two months she was quite cured. Schreger has described this Bursa, but has given no drawing of it; he does not seem to have met with it in a diseased condition.

There is usually a distinct Bursa over each malleolus; but the external malleolar Bursa is the one most liable to be enlarged or distended with fluid. At one time it was thought, that in club-foot an accidental bursa was formed, to protect the integument at the point of greatest pressure; but this notion has been distinctly refuted. A Subcutaneous Bursa, occasionally of considerable size, very generally exists over the distal extremity of the metatarsal bone of the great toe, close to the joint, and the term bunion has been applied to it when inflamed or thickened. Subcutaneous Bursæ are met with over the trochanter major and tuberosity of the ischium, in the groins, and in connexion with the lower part of the superficial fascia of the abdomen.

Bursæ of this kind exist also, as has been already mentioned, in the axillæ, and over the condyles of the humerus. An enlarged Bursa over the inner condyle of the humerus came under my notice. C. W., æt. 18, applied to me on the 18th August, with a swelling over and a little above the inner condyle. As the patient, a few days before, was stooping to raise something heavy from the floor, he first felt pain in the part, and shortly afterwards discovered a slight swelling. At first, it was like a small indurated gland, but it gradually increased to the size of a walnut. It was unattended with pain, and gave, on pressure, an elastic indistinct fluctuating feel. On the 3rd September, I punctured it, and there exuded about a tablespoonful of transparent gelatinous fluid. Firm pressure was applied, and removed from time to time, and the swelling has not returned.

The Bursa which we may call anconal, as situated over the olecranon, is well known, and is often enlarged. There is also one over the distal extremities of the radius and ulna, and one on the carpus, corresponding to the surface of the os magnum, which is often enlarged. A girl, 13 years of age, applied to me on the 7th September, with a swelling like

a large marble, which had existed six months, and was situated on the posterior surface of the right carpus, over the os magnum. I punctured it with a grooved needle, evacuated a teaspoonful of white vitreous looking fluid. Pressure was applied over the part, and renewed every week for three times. The patient is now quite well.

That Bursæ in this situation may sometimes acquire considerable size, is shown by the following case. E. F., æt. 30, applied to me on November 15th, on account of a large Bursa over the os magnum, and a little to the radial side of it. About eight years ago it first arose, from her husband pressing this part of her hand very hard with his knuckles,—to use her own expression, by "his knuckling her". Immediately after this a swelling commenced, and at the end of a twelvemonth it had attained the size of a walnut. It was then punctured, and near two teaspoonfuls of fluid were evacuated. No pressure was applied; the swelling disappeared, until two years ago, since which time it gradually increased, till it reached the present size. The swelling prevented her from turning her hand back, and from wringing clothes. There was a great feeling of weakness in the joint, and occasional pain in and about the swelling, especially after exertion. On November 18th, I punctured it with a needle. As the case is still under treatment, I am unable to give the result: I feel no doubt, however, of its permanent dispersion.

There is a large Bursa over the first joint of the thumb, and others, often double, over the first and second joints of the fingers. That Bursæ exist in other parts of the body, I have no reason to doubt; one is not unfrequently found under the integuments, at the angle of the jaw; and others, extremely minute, and rarely demonstrable, are said to exist under the integuments of the back, corresponding to the spinous processes of the fifth, sixth, and seventh cervical vertebræ. More extended pathological inquiries may enable us still to discover others; for it is by their accidental enlargement that the presence of some of them has become known to surgeons.

Symptoms and Diagnosis of Enlarged Bursæ. A correct knowledge of the situation, volume, form, and position of the superficial or Subcutaneous Bursæ, will, on most occasions, enable the surgeon to appreciate the character of a tumour due to an increased secretion of the fluid in the interior of these sacs, to a thickening of their walls, or to an inflammatory action set up around or within their tissues. The symptom which naturally first attracts attention, is the existence of an oval, colourless, elevated swelling, in an unusual situation. Should the surgeon happen to be ignorant of the previous existence there of an original Bursal apparatus, for the protection of the integuments and for facilitating motion, he is at first lost in conjectures as to what the swelling may be. This has often happened. But, aware of the existence of the superficial Bursæ, and of the localities which they constantly occupy, the first glance at the case not unfrequently reveals to him all he requires to know. I need not therefore dwell on this symptom, remarking merely, that the tumour may be small or large, moveable, colourless, or deeply inflamed; or occasionally ulcerated on its surface, and discharging pus and serous looking fluids; or, by long neglect and the influence of time, it may appear as a firm unyielding tumour, without fluctuation or elasticity.

Even when uncomplicated, the enlarged Bursæ occasionally, though not uniformly, give rise to symptoms meriting attention in a history of these affections. A certain amount of inconvenience is often felt, varying in intensity with the volume, situation, and condition of the swelling. The enlarged anconal Bursa, for example, may attain a considerable size, and yet give rise to no more inconvenience than a slight sense of weakness after fatigue; even the patellar Bursa may be enlarged without proving troublesome to the patient. But in others, and these, perhaps, form the majority, it is otherwise. Those in the hand, especially the carpal, cause a great sense of weakness; they are unseemly, and the deformity becomes so unpleasant to the patient, as to induce him to request the removal of the swelling at all risks. In like manner, those over the malleoli deform the foot, and cause other inconveniences. Much lameness often accompanies the enlarged patellar Bursa; whilst the enlargement of the Bursa over the first joint of the great toe, produces not unfrequently the most intense suffering. Inflammation and suppuration follow; and death has been known to supervene from such a course, when injudiciously interfered with by the surgeon. Generally speaking, then, the symptoms indicating the presence of an enlarged Bursa are sufficiently well marked to lead to a correct diagnosis.

A knowledge of the course of the tendons will enable the surgeon to discriminate between an enlargement of a superficial Bursa, from that more troublesome and dangerous affection, the enlargement of the deep or profound; and he will regulate his treatment accordingly. Of these I do not speak at present, confining my remarks wholly to the system of the superficial Bursæ. These swellings, then, interfere with the free use of the limbs in which they happen to occur. The integuments may inflame and suppurate, and in this condition the case may for the first instance be brought to the surgeon. If neglected now, they cause intense suffering. The cause of the pain is not uniformly the same. In the enlarged Bursa over the great toe, for example, considerable pressure may be endured, provided a corn has not happened to be induced by that pressure over the enlarged Bursa. When this happens, the pain becomes intolerable, and is seemingly disproportioned, if I may say so, to the other symptoms and appearances; but it is well to know this, for the partial removal of the corn by the knife will often give immediate and great relief. A very usual symptom is a tingling sensation running down the limb, often attended with tenderness on pressure.

The position of the enlarged popliteal Bursa necessitates a careful diagnosis; it may be mistaken for abscess, or for other still more dangerous affections. It is sufficient merely to caution the surgeon on this point.

The detection of enlarged Bursæ in the axilla, and in the groins, and the discriminating them from other diseases, will occasionally require great attention on the part of the surgeon.

Enlargements of the superficial Bursæ have frequently, no doubt, been confounded with encysted tumours; their sequelæ also present difficulties in the way of a correct diagnosis, to be overcome only by a careful observation and history of the case.

Enlarged Bursæ may be either simply enlarged, or the enlargement may be accompanied with inflammation and all its usual appearances.

Erysipelas may arise in the course of the disease; or at least, œdema of the superficial fascia or cellular layer, in which the Bursæ are situated.

Pathology. The morbid anatomy of this system of organs has not been made the subject of any extensive researches. What has been observed amounts to this: the contained fluid, which in health merely bedews the surfaces of the sac, increases in quantity and alters more or less in quality. Originally, perhaps, more complex than chemists suppose (such at least seems to have been the opinion of Schreger), it may undergo further changes, as a result of chronic or acute inflammation. At times, the fluid resembles the outer layer of the crystalline lens, or the vitreous humours; that is, it partakes more of the character of a semi-solid than of a liquid; at other times, it is much more fluid, or it is more serous, obviously less abounding in albumen.

The semi-fluid substance has sometimes a yellowish appearance, at other times a reddish hue; sometimes it is very fluid, of a dark, dirty colour, the product, no doubt, of an inflammatory action. The sac may be wholly obliterated, or its walls so greatly thickened and condensed as to represent a solid tumour; or the enlarged Bursæ may shew a dropsical character, with softening of the inner membrane, perforations, and enlargement of the traversing tendinous cords. The absence of many of these Bursæ may depend, no doubt, on their obliteration in early years from blows, pressure, or other accidental violence.

The morbid appearances found in connexion with the enlarged Bursa of the great toe, have little or no reference to the smaller Bursa itself, but to the deformity caused by the simultaneous displacement of the metatarsal and digital bones of the toe. Nevertheless, when, by a separation or spreading out of the distal end of the metatarsal bones, the head or extremity of the first metatarsal bone becomes so prominent on the inner side of the foot as to be mistaken for an osseous tumour, the integuments passing over it become much attenuated in those cases where the deformity occurs in the adult. If congenital, or occurring in early years, no such attenuation happens. The Bursa itself, on dissection, presents a variety of morbid appearances, according to the progress made by the displacement of the metatarsal bone, and of the phalanges of the toe. The ligaments also undergo changes, but I cannot say that I have ever observed the formation of accidental Bursæ amongst their fibres. Fungous growths have been seen growing from the inner surface of enlarged Bursæ; and ill-conditioned sores are also sometimes present, depending partly on the nature of the surfaces affected, and partly on the constitution of the patient.

Causes. A variety of causes likely to produce enlargement and subsequent disease of the superficial Bursæ, have been stated by systematic writers. Unfortunately, however, by confounding these organs with the deep Bursæ and synovial sheaths of tendons, or by a meagreness of detail, many otherwise interesting observations have failed to improve our knowledge of the disease. The formation of accidental Bursæ I have shewn to be, in every instance, doubtful, whether on the prominent part of the spine in deformities of this column, or in any other part of the body. The inflammation and enlargement of the Bursæ over the great toe, happen how it will, is merely an enlargement of a Bursa already existing there, and not a new formation.

Enlarged Bursæ are frequently ascribed to severe pressure, sudden or long-continued, to blows, or other external violence; and to such a cause, no doubt, many cases may be traced. At other times, Bursæ enlarge wholly independent of any such causes. It has been usual to speak of the enlarged patellar Bursa as "the housemaid's knee," of the enlarged anconal bursæ as "the miner's elbow," etc.; but many cases of enlargement of the Bursæ cannot be so explained. Thus, then, they not unfrequently originate without any assignable cause. It has been said that corns and bunions (diseases very opposite in their nature, though, strangely enough, associated in surgical works), and enlarged Bursæ, ganglions, and tumours, are much more numerous in the rich than the poor; of this, however, I have my doubts. The mechanical causes assigned for the production of the enlarged Bursa over the great toe, and for the deformity of the foot, so frequently preceding re-enlargements of the Bursa, and giving rise to it, can be distinctly refuted. I allude more especially to the theory, that such deformities and diseases are caused by tight shoes.

It merits notice, that those who stand out most for the efficacy of mechanical causes in the production of such diseases, have uniformly avoided offering any explanation of the circumstance,—that the disease I have just alluded to (enlarged Bursa in the deformed foot), appears first not unfrequently in one foot, and is even confined to that foot, be it right or left; but if a rigid shoe were the producing cause, both feet ought clearly to be affected simultaneously. Again, when enlarged Bursæ occur, which cannot be traced to any mechanical injury, it not unfrequently happens that they occur at once in both limbs; this need not surprise us, as the laws of symmetry go far to explain the occurrence. Some have carried the idea of the production of enlarged Bursæ by accidental causes so far, as to include under the same category the actual formation of the healthy sacs, creating the system whose nature I now describe. They have also found Bursæ in situations where I cannot say I have ever observed them; namely, around corns, and between these semi-horny productions, and the true skin: but no such productions exist so far as my observations go, nor are they required to explain the intense suffering arising from pressure over a corn. The wedge-shaped body is at that moment slowly, but surely, growing inwards, piercing the true skin, and tearing its delicate structures asunder. Take off the pressure, or remove the offending wedge, and the pain ceases.

Treatment. It has been shown that many of the Subcutaneous Bursæ of the body are occasionally wholly absent, or, in other words, never were present. In this sense, then, they are not essential structures, at least, not in these persons. But it has also, I think, been proved that such Bursæ, when enlarged, may be obliterated by pressure, or the same result may be effected by pressure and puncture combined; or by inflammation, suppuration, granulation, and consequent adhesion of surfaces; or lastly, when, losing their original character, they have attained, by means of fibrinous deposits, the appearance and nature of a solid tumour, they may be extirpated by the knife, and so altogether removed. These considerations, aided by a sound anatomy and physiology, which we owe chiefly to Schreger, have led me to the adoption of a simple mode of treatment, applicable to most, if not to all cases, of enlarged Bursæ.

Let me first suppose, that a case of enlarged Bursa, unaccompanied with any other affection, no matter where placed, presents itself; that of the great toe need form no exception; an enlargement of the natural patellar, anconal, or malleolar Bursæ; the question arises, how is it to be treated? Abundance of evidence exists to shew, that the treatment by rest and pressure, simple friction, blistering, friction with mercurial ointment, iodine, etc., all but uniformly fail in effecting a permanent cure.

When these fail, recourse is had to a puncture, which, made with a lancet, amounts generally to a short incision; or an incision, more or less extensive, is made into the enlarged Bursa, the contents evacuated, and pressure applied. This method, no doubt, succeeds; but it is unnecessarily severe, and is not unattended with danger, even in the uncomplicated class of cases. But it not unfrequently happens, that before the surgeon has seen the case, inflammation of the integuments, and of the superficial fascia in which the Bursa lies, has set in, with more or less severity. Now, in such cases, the modes of treatment alluded to are clearly inapplicable, and have occasionally been attended with very serious results.

Mr. Key, in an excellent memoir on ganglia or bunion, distinctly refers to a case, in which death happened from the incautious interference of the surgeon. He is speaking of the enlarged Bursa on the great toe, which complaint, when complicated with the peculiar deformity I have already spoken of, he calls bunion. "I have known", he says, "gangrene of the foot and death ensue from opening an inflamed and suppurating bunion; and in three cases, exfoliation of the bones, with a most tedious and painful suppuration of the surrounding structures". He condemns all interference in such cases, in which opinion I coincide, although maintaining very different views, as to the nature of the affection, from those of the distinguished surgeon whom I have just quoted.

The mode of treatment which I prefer to all others, is simply puncturing of the enlarged Bursa with a grooved needle, such as is used for exploring tumours and swellings of doubtful character. After the evacuation of the contents, pressure is applied, by means of soap-plaster and bandage; this is renewed from time to time, and puncture of the sac repeated if necessary. The result is uniformly a permanent and safe cure. If to this we add the almost painless nature of the operation, we have in this mode of treatment all that is satisfactory to patient and surgeon.

When the enlarged Bursa becomes seriously inflamed, we should endeavour, by rest and other means, to subdue the inflammation: nevertheless, a puncture such as I have described may be practised, even in these cases, with advantage to the patient.

In a case of anconal Bursa, accompanied by high inflammation, I punctured the swelling with a grooved needle; pressure was employed; no bad results followed, and the patient recovered. Miss M., æt. 50, applied to me, October 18th, with an enlargement of the Bursa over the right olecranon, the skin being highly inflamed. The inflammation had existed for ten days, and became so severe as to compel her to seek advice. I punctured it, and two teaspoonfuls of dirty looking serous fluid came out; pressure was applied, and at the tenth day she recovered.

Sometimes the integuments over the Bursa ulcerate, and under these circumstances, pressure may also be employed, as in cases of simple puncture. In cases of long standing, when the enlarged sac has put on the appearance of a sarcomatous tumour, excision is no doubt the remedy, having a due regard to the integuments. The mode of treatment by the seton has been strongly recommended by many good surgeons, and I have myself adopted it with success; but a more enlarged experience has convinced me that this mode of treatment, besides being a tedious and unnecessary process, is not on all occasions unattended with danger. I think it only applicable to those cases where the question arises as to their destruction by the seton, or removal by the knife.

The following interesting cases were communicated to me by my friend, Mr. Cocks, of Hatfield, who has kindly permitted me to publish them.

"I had", says Mr. C., "for several years, an enlarged Bursa on the second joint of the left thumb, produced by a blow on the fore part of the saddle, in checking the bridle of my horse. It became as large as a pea, and was rather annoying and unsightly; I punctured it with a lancet, when a pinkish crystalline mass came from it; pressure was applied, and it healed. It soon grew again, and again, and the same operation was repeated. But, tired of this plan, after opening it, I rubbed the inside with a camel's-hair brush, dipped in a solution of nitras argenti (4 grs. to ʒj of water). In a few days, it suppurated; the lining membrane sloughed away; it soon healed, and has been so for more than a year. The next case was under my son. A servant girl, from London, had a very large Bursa on the left outer ankle, just below the end of the fibula, stretching across the dorsum of the foot, about two inches long, and at least an inch wide. She had applied to several medical men in town, all of whom advised 'nothing to be done'. It was opened by my son; solution of nitrate of silver was injected into it, and pressure by compress and bandage applied. In a few days, the greater part of the sac was obliterated; the fluid (which in this was limpid) collected in the non-adhering portion. The same treatment was applied to this part, which was followed by considerable swelling of the foot and leg. The inflamed leg was treated with cold saturnine lotion; but a warm poultice was applied to the tumour, in order to bring on suppuration as soon as possible. The case went on favourably; and in three weeks she was able to go about quite well".

No cases of enlarged Bursæ have attracted more attention than that of the great toe; when painful and enlarged, it is difficult to treat, for reasons I have partly explained. So much confusion prevails in surgical works, as to the true nature of the proper method of treatment of this troublesome Bursa, when enlarged and inflamed, that I may hope to be excused, if I again direct attention to it. The Bursa situated on this part may become enlarged and painful, like any other superficial Bursa, and require, for its relief and cure, the treatment I have recommended. But that which, in a peculiar manner, complicates the pathology of this enlarged Bursa, is the accidental deformity, caused by a projection inwards of the digital extremity of the first metatarsal bone. The phalanges of the great toe itself turn outwards to such an extent as to over-

lap, or pass under, those of the second,—a deformity, in fact, amounting to all but complete dislocation. As the metatarsal bone recedes more and more from the second, the digital extremity seems to enlarge, causing a remarkable prominence inwards of this part of the foot.

In the mean time, as the deformity increases, the bursa is placed, daily, under pressure, more and more severe; the same shoe no longer fits the form of the foot, now much broader in the distal extremity of the metatarsal region; the Bursa enlarges, and becomes extremely painful. A succession of Bursæ form on the same spot; they open, and perhaps suppurate: and cases are stated to have occurred in which the joint itself has been laid open, and caustic applied to the inner projecting portion of the metatarsal bone, as if it were of morbid growth.

The disease, then, in its most aggravated form, that is when complicated with this deformity, consists, simply, in an inflamed Bursa, generally produced by pressure, with a partial dislocation of the great toe, mainly dependent on a displacement inwards of the digital end of the metatarsal bone. As these two affections are quite distinct, though often confounded, I need not here inquire as to the causes giving rise to the deformity. It will be sufficient to observe, that tight shoes, or rather shoes no longer fitting the altered form of the foot, however they may give rise to an enlargement of the Bursa, in no case produce the deformity; for it is now universally admitted that the deformity is most frequently congenital, or comes on in very early life; that it occurs in hundreds who never wore shoes, or boots, and that, even when present, it does not necessarily give rise to enlarged Bursæ. The cases which most frequently came before the surgeon, occur in persons who get the deformity after the meridian of life. The deformity takes place as a result of the weakening of those structures binding together the metatarsal bones; the larger one recedes from the second, and the muscular forces, acting on the great toe, assist in adding to the deformity, by causing it to approach the others. The treatment of such complex cases is exceedingly difficult. It is here that rest, in the recumbent posture, becomes absolutely necessary; the inflammation must be subdued, or allowed to subside. Should a corn have formed on the enlarged Bursa, it had better be cautiously pared down, as the skin has probably become much thinner over the Bursa. When the foot has become tranquil, other questions arise as to the treatment, chiefly bearing on the form of the shoe; a boot, properly made of very soft leather, such as is worn in France, may be used without aggravating the complaint. Shoes, I apprehend, are bad, as they necessitate a somewhat tight ligature over the instep; this causes intense pain immediately below it, or nearer to the toe. In time the integuments may and do become accustomed to the form of the foot, and the Bursa no longer enlarges. This, I think, is the ordinary course of events, even in cases, by no means unfrequent, where the deformity has proceeded to its greatest extent. When the deformity is natural to the person, the Bursæ do not naturally enlarge, and therefore give little or no trouble.

ON THE EPIDEMIC OPHTHALMIA

WHICH HAS PREVAILED IN THE WORKHOUSES AND SCHOOLS OF THE TIPPERARY AND ATHLONE UNIONS.

By WILLIAM R. WILDE, Esq., F.R.C.S.I.,
Surgeon to St. Mark's Ophthalmic Hospital, Dublin; and Assistant Commissioner for taking the Census of Ireland in 1851, etc.

Some notice of my reports to the Poor-Law Commissioners upon the Epidemic Ophthalmia which has prevailed for some time in a few of the Irish workhouses having already appeared in the newspapers, and a few detached fragments having been surreptitiously obtained and erroneously printed for the purpose of review, I am induced to write the following observations, and to give a corrected edition of my *Medical Report* to the profession. I have but few remarks to make with respect to the observations appended to the fragments which have been published elsewhere. They are these:—I was applied to, in the beginning of December 1849, to visit and report on the Ophthalmia which then raged in the Athlone Union. I did not do so, because I did not consider the sum offered a sufficient remuneration for my professional services. Upon inquiry, I have been informed that, in accordance with my desire, a copy of my letter to the Medical Officers of the Tipperary Union was forwarded by the Commissioners to the Medical Attendant of the Athlone Workhouse, which I visited a few days after I had been in Tipperary, and where the same form of disease prevailed; and that, in other instances, it was applied for by the medical attendants themselves.

With respect to any previous reports which may have been made to the Commissioners upon the Ophthalmia, I have nothing whatever to do. If the guardians of any particular union do not choose to adopt, or the Poor-Law officials to enforce the recommendations and suggestions contained in a report, no medical man should take offence thereat, any more than he would with a patient in private practice, who sought his advice, received his prescription, and paid the usual fee, but either from perverseness, indolence, or want of faith in the proposed remedies, or in the mode of recommending them, gave no further attention to the matter.

It was not my original desire or intention to write upon this Ophthalmia, but to leave to the Poor-Law authorities, to whom they belong, to publish my Reports or not, as they thought fit, in their own proceedings: but the use lately made of my letter to my medical brethren (not of the Athlone, but of the Tipperary Union, on which alone I was called on to report), has compelled me to adopt the present course. I cannot, however, but feel complimented by finding any one generous and philanthropic enough to print and publish at their expense any portion of my writings, no matter how obtained; and I only regret, that such publication was not through a medium where it might have had a more extensive circulation. How far that letter is in accordance with the established rules of consultation communications, and professional etiquette, even where private patients are concerned: and how far the statements and recommendations contained in it are based on modern observation, and the scientific management of the disease under consi-

deration by the most enlightened ophthalmic surgeons of the present day, the medical profession are the best and only judges. It is gratifying to me to be able to state, that the medical officers of the Tipperary Union not only willingly adopted all my suggestions, but have, in a written communication, expressed their satisfaction at the course which I pursued. The notes now appended to my Medical Report are the only additions made to it since it was sent to the Poor-Law office. Neither has it in anywise been altered or amended, except so far as the usual corrections of the press required.

The lamentable consequences of the Irish epidemic do not seem to be the result of any defect in the Poor-Law, any more than the ravages committed by the Egyptian Ophthalmia among the soldiers of the British Army in 1803 arose from the inadequate resources of the Minister of War, the defective regulations of the Horse-Guards, or the ignorance of and insufficient treatment adopted by the medical officers. In both Tipperary and Athlone, the local guardians were superseded, and vice-guardians appointed; but whichever they are, the guardians of the Irish poor, paid or unpaid, should learn that it is neither justice to those entrusted to their care, nor economy to the rate-payers, not to provide suitable accommodation and other necessaries for the miserable patients, affected with a disease like that on which I have been called on to report. If it were a fatal disease, the result, according to the doctrines of some, might justify the means,—at least the mortality would lessen the expenditure; but it is not so. By this disease, people are only rendered incapable of earning their livelihood, and, in some instances, of ever leaving the workhouse; and so they remain a permanent tax upon the union. It should also be generally known, that blind people are remarkably long-lived. It, therefore, behoves the guardians and local authorities of our Irish unions, calmly and gravely to calculate the probable expense of the support for life of blind persons under twelve years of age, before they allow them to be crammed by hundreds into an unhealthy store or a damp sunken malthouse. To some very philanthropic persons, the doctrine may appear revolting and uncharitable; but it does, nevertheless, appear to me inconsistent to decorate the dead body of a pauper in the paraphernalia of shroud and coffin, merely in compliance with popular usage, while the living pauper is unfurnished with the means of retaining that health and those senses, without which there can be no hope of his ever regaining independence.

Many a good soldier, not slain in battle, has been, and is still, carried to his "rest" with "his martial cloak around him", without exciting the indignation of his comrades! Some outcry may perhaps be made by well-meaning, but uninformed persons, on account of the number of people who have lately become blind in the Irish workhouses. Before, however, such persons come into the field, they should require from the Horse-Guards an accurate statistical return of the number of soldiers who, after a considerable sum of public money has been expended on their training, and, as frequently happens, their transport to the Colonies, are annually invalided, and sent home either totally blind and so entitled to a pension for life, or partially deprived of vision and furnished with a pension for a limited period; and, be it remembered, the blindness under which they labour has arisen from the very same disease as that which has spread through the paupers in some of the Irish workhouses,

It must be borne in mind, that the observations contained in this paper are of a special, not a general nature; applicable to a peculiar affection appearing under circumstances, and among a class of people, such as neither this nor any other so-called civilized country ever presented before. Did not the late "famine fever," as it was termed, and the dysentery present such peculiarities as never had been observed in any of our previous epidemics? I was called on to report, not on Epidemic Ophthalmia merely, but on the exact condition and the best method of arresting the disease under which the paupers in certain districts laboured. To occupy any portion of this paper with pages of extracts from the writings of Vetch, Saunders, Mackenzie, Lawrence, and others, whose works are accessible to the profession, or to give a *réchauffé* of opinions and descriptions promulgated a quarter of a century ago, would partake more of system-making and book-learning than observation. I shall therefore confine myself as much as possible to facts of which I have been myself cognizant, or of which I have received accounts from credible authorities.

OPHTHALMIA IN THE TIPPERARY UNION.

In compliance with the request of the Poor-Law Commissioners, I visited the Union Schools, the Auxiliary Workhouse, and the Ophthalmic Hospital at Tipperary, upon the 12th of last August, and those at Athlone on the 23rd of the same month. From the evidence which I received, and from my own observations in the neighbourhood of the town of Tipperary, it would appear that an Epidemic Ophthalmia had for a considerable time prevailed among the lower orders in the adjoining country parts. The injurious effects of this disease, in the form of complete loss of one eye, staphylomata, leucomata, opacities of the cornea of various shades, and chronic Ophthalmia, etc., were manifest in a great number of the people I encountered; particularly in those emaciated and broken down in health, whom I saw in the town of Tipperary. Indeed I was strongly reminded during the day I spent in Tipperary, of scenes I witnessed many years ago in the bazaars of Egypt.

From the account given me by the physicians of the Union, it appears that the disease first commenced among the pauper children of the girls' school in the town of Tipperary, in the spring of 1849, and that it went on progressing until October in that year, when it assumed a more violent and decided character, so as to require their being removed for treatment to a separate house, the ordinary hospital of the parent workhouse being so much overcrowded as not to permit of their reception. What number of persons labouring under Ophthalmia were treated in the wards of the workhouse hospital between spring and autumn in the year 1849, I have had no means of ascertaining. A separate hospital becoming necessary for the reception of Ophthalmic patients, the guardians hired an unoccupied house with an adjoining store, in the town, for that purpose. At the time of my visit, it had been given up upon the recommendation of the medical men and the inspector, and the children had been removed to a much more healthy locality; but I nevertheless inspected it and reported upon it to the Commissioners, in the hope that some means will hereafter be taken by the Poor-Law authorities to prevent the guardians and local officers,

many of whom are quite unacquainted with the value of pure air, cleanliness, warmth, proper ventilation, sewerage, and other sanitary matters, in arresting the progress of disease, or contributing to the comfort of the diseased, from again falling into like errors. I am fully conscious of the difficulties which beset this subject, and of the ignorance as well as the apathy which prevail upon it among all classes of the community,—an ignorance and an indifference lamentably exhibited, even in the private dwellings of some of the middle and better orders of society,—as every medical man engaged in extensive practice is well aware. Who amongst us has not daily to enter houses where he is immediately assailed with a stench of sewers, kitchens, areas, and privies? I need not describe the scenes which meet him in his further progress to the dormitories, within the dark confined space of one of which may be found his patient, scarcely visible amidst the voluminous coverings of a feather bed. The bed itself, surrounded by thick close-drawn curtains, is generally one half the size of the room, and the air of the apartment is at times stifling in the extreme. If a Poor-Law guardian is willing to let his wife or child stew out a fever or a pneumonia under such unhealthy circumstances, we cannot expect him to provide wholesome accommodation for the pauper. But the authorities in a distant town or country village can scarcely be blamed for such matters, when we remember the condition in which the poor of Dublin were left at the fever-sheds in the beginning of the frightful epidemic of 1846, until attention was called to the subject by my lamented friend, Dr. Curran. Nor can we well exclaim against guardians and inspectors for defective ventilation in auxiliary workhouses and temporary schools, when, in some of the first-class houses of the metropolis, partial congestion is daily experienced by those who sit out a crowded dinner under the heat and glare of six or eight gas-burners placed in different parts of the room, without a single aperture in the ceiling or walls to permit any portion of the vitiated air to escape!

What is to be done, when an epidemic of an infectious character suddenly either springs up among the people, or spreads within the workhouse or its schools? Separate accommodation must be procured. Tents and sheds have been the usual means employed by Boards of Health and other authorities in such emergencies. For fever and dysentery, these may be applicable during the warm months of summer; but the localities for their erection should be properly chosen, in order to prevent such an accident as occurred at Navan during the last epidemic of fever, when, owing to their exposed situation, several of the fever-sheds were swept away one night, and some of the miserable patients left uncovered during the hours of storm and rain which followed. When an epidemic like Ophthalmia, affecting children and young persons, or when cholera, or any similar disease, which cannot be well treated in temporary sheds, breaks out, the only resource left for those who have to provide for the poor, is to hire a house, the first that can be had; and as few persons are willing, even at a high rent, to let their houses for hospitals, the consequence is, that *of necessity* old dilapidated dwellings long unoccupied, mills, corn stores, breweries, and such other buildings, with low, ill-ventilated lofts, and unprovided with sewers or privies, are really the only ones which can be procured. But still, some of the modern knowledge in sanitary matters, so much boasted of by the learned, and at

present occupying both the public mind and the attention of the legislature, should be put in force, to render these buildings as wholesome as possible under the circumstances. I therefore, in my Reports, impressed upon the Commissioners the necessity of appointing some proper officer to see that such matters are strictly attended to, both in the choice of a locality, and in the best mode of turning a store or dwelling-house into a suitable hospital. The majority of guardians in Ireland at present know nothing of such things, and even if they did, might be unwilling to encounter the necessary cost. Inspectors are uneducated in sanitary concerns; and until a course of lectures upon hygiene, somewhat similar to that required in the army, is made a part of the curriculum of education by our schools and licensing bodies, we cannot expect the medical men of the civil service to be thoroughly acquainted with the best mode of applying all the modern improvements of science to the construction of hospitals, their heating, ventilation, lighting, etc., etc. Certain it is, that it would not only be just and merciful towards the poor, but in the end, economical to the rate-payers, to procure the services of a person educated in medicine and hygiene as well as in architecture, in order to fit up these temporary hospitals. I do not consider these observations a digression from the matter in hand, and I have been induced to make them, from the impression which I received on visiting the temporary hospitals provided for ophthalmic patients at Tipperary and Athlone. Upon inquiry at both these localities, why the hospitals which I visited were chosen, the answers were, that they were the only ones which could be procured at the moment;—good; but much more could have been made of them if such a system as I have suggested had been carried out. With respect to the influence of the medical officers of the Irish workhouses generally, it must be remembered that they can only suggest, that they cannot enforce, and they are frequently the family attendants upon the guardians and other officials, as well as the rate-payers, and moreover, that their income is more or less dependent upon these persons.

In answer to a series of questions which I addressed to Dr. W. T. Reardon, the assistant-physician who has had charge of the ophthalmic cases at Tipperary, he informs me, and his answers are confirmed by my own observations, that "the class of patients attacked were debilitated starved female children; generally those recently admitted, worn out by previous want and privation of every kind, many having refused to come into the house in consequence of its crowded state, until they were exhausted to the last degree. Several were admitted this year (1850) labouring under Ophthalmia; some had already lost one eye, and the other was in a state of violent inflammation. The general health of the workhouse was very bad indeed; we had cholera, dysentery, fever, and small-pox, as well as several cases of gangrene and dropsy. There was no proper sewerage, neither was there sufficient water to cleanse the entire house or purify the privies, except what a horse brought daily from town. The vice-guardians got some sewers made; but from these being frequently opened to admit others, the smell from them was very foul. The deaths in the workhouse, since spring, have been very numerous, the mortality varying from thirty-six to fifty weekly. Few men had the Ophthalmia; I would say, not one healthy man contracted it, and very few healthy women, except the wardmaids."

From October 1849 to March 1850, there were 1525 cases, 848 males and 677 females, treated in the Jail Lane hospital of Tipperary. In consequence of the representations and remonstrances made to the Poor-Law Inspector by the physicians, to the effect that it was impossible to afford the necessary treatment to the unhappy inmates of this establishment, it was closed upon the 18th of July last, and the 302 patients whom it contained were removed to a large building in Meeting-house Lane, also in the town of Tipperary, and which was originally built for a corn store. Although the building used as an hospital in Jail Lane had been given up, and consequently did not contain patients, I conceived it to be my duty to visit the premises, in order to point out to the proper authorities how unsuited it was to the purpose intended, in the hope that, by so doing, the like occurrence might be prevented in future. I likewise entered into a minute description and admeasurement of the newly-formed Ophthalmic Hospital in Meeting-house Lane, shewing that it was improperly ventilated, heated, and lighted, that its wards were, from the very nature of the building, quite too low, and that it was most disadvantageously situated, having but a most imperfect sewerage, not possessing a proper privy, but in lieu thereof, a moveable one, by means of a soil-cart; and that the yard, the only place in which the children could take exercise, was quite too small, being but twenty-four yards long by twenty broad, surrounded by high walls, one of which was the side of the Dysentery Hospital. I pointed out such means as appeared to me absolutely necessary, to render this hospital habitable during the ensuing winter; but I also strongly urged upon the Commissioners the propriety of recommending the guardians to take a country place, the residences of some of the neighbouring gentry (so many of which are now unhappily vacant in Ireland), to which all the children should be removed as soon as possible. In an Essay such as this, it is unnecessary for me to enter into the same minutiæ with respect to those defects in the establishment, as I detailed in my Report to the Commissioners; but it is of great importance that those who are the legal guardians of the poor should understand, that where a vast number of persons, whose health and spirits have been previously broken down by want and privations of every description, are congregated together, attention to cleanliness, diet, clothing, lodging, warmth and ventilation, the means of taking exercise, and some provision for amusement or occupation, is of as much, if not of greater importance than any merely medical treatment that could be adopted. Such treatment, after all, must be based upon some general principle, and cannot, certainly, with the small staff of attendants allowed by the guardians, enter minutely into the circumstances of each individual case. The yard of the hospital, although clean and well gravelled, was totally insufficient for the children to take proper exercise in: I therefore recommended that such of the children as were convalescent should be sent out into the fields daily to play, and that gymnastics and other means of amusement should be provided, until proper accommodation were procured for them in the country.

There had been 241 new cases admitted since the hospital was opened, making in all 2068 cases of Ophthalmia in the Tipperary Union, between the 29th October 1849, and the day of my inspection,—the 12th of August 1850. I found 340 patients, 170 boys and 156 girls, aged from five to fourteen years upon an average, and 14 adults, in hospital. My first

business, after having inspected the premises, was to procure a registry, by means of one or two intelligent clerks, of the name, age, and sex, of every inmate, in order that I might attach such observations to each entry, as would enable me subsequently to draw up a statistical report upon the condition of the disease in the workhouse generally, and on the present effects as well as probable results of the Ophthalmia in each individual case. Without such documentary evidence, I believe it would be quite impossible to make anything approaching to an accurate statement, as to the result of an epidemic of this nature in three hundred and forty cases. Moreover, vague rumours spread with respect to the number of persons who become blind in such and such unions; and, as even medical men will differ on such subjects, and consequent discrepancies appear in reports, I would impress upon persons similarly engaged, the propriety of adopting the means which I have described for registering the cases. And as an unjust outcry of this nature might be raised against the permanent medical attendants, I thought it right that the commissioners and guardians should distinctly understand that the meaning to be attached to being "totally blind" was,—that both eyes had either become wasted and collapsed, or so much disorganized as to render all hope of vision irredeemable. But there are now many persons in the workhouses, with closed pupils, extensive leucomata of the corneæ, etc., the results of the Ophthalmia, at present depriving them of vision, who may hereafter, by treatment or the effects of nature, recover a fair amount of sight. Thus, in those whom one practitioner considers at the moment "blind," another may see a fair hope of recovery by operation or otherwise, and each will, consequently, place such persons in a different category. The admissions into the hospital from the 30th of March to the 20th of August, varied from 17 to 70 weekly, the disease appearing to increase with the warm weather. Statistical statements such as this, where I myself could not have been aware of the facts, were kindly furnished me by the assistant-physician who has had charge of the Ophthalmic Hospital.

In company with the medical attendants, Dr. Evans and Dr. W. T. Reardon, I then proceeded to examine the cases individually, and to consult with these gentlemen as to the treatment to be pursued, and the best mode of arresting the further progress of the epidemic; and with their *sanction* and *concurrence* I addressed to them the letter which will be found appended to this communication, and of which such unwarrantable use has already been made for private purposes. If the Poor-Law authorities, having been officially informed that Ophthalmia is spreading among the inmates of a certain workhouse or its schools, forward a copy of that letter to the medical attendant thereof, it remains for him to judge how far the disease, which I have described, is the same in those persons under his care, and to exercise his judgment with respect to his adopting the suggestions conveyed, at their desire, to my medical brethren in Tipperary.

Among the 340 patients, each of whom was individually inspected, were to be found cases of Ophthalmia or its results in all stages, from those recently affected either with simple conjunctivitis, muco-purulent Ophthalmia, or the more violent and purulent form of the disease, to those presenting collapsed globes, or staphyloma, either of the cornea and iris, or of the entire eye; but the vast majority laboured under chronic

Ophthalmia with granular lids, and a great many presented ulcers of the cornea, some of which had just penetrated, thus allowing a small portion of the iris to protrude. The granulations upon the conjunctival surface of the upper lid were the largest I ever witnessed, many of them exceeding in magnitude the size of a split pea, and some resembled the protuberance which forms upon the end of the divided muscle after the operation for strabismus; or were like the little fungus nail-headed excrescence, which grows from the conjunctiva of the lid in cases of neglected tarsal tumour, attached by a peduncle, and capable of being removed with facility by means of a curved scissars. In some cases, several of these existed along with the general villous or granular condition of the conjunctiva; they were principally congregated above the external canthus; and to such an extent had they grown, in some instances, as to produce a manifest protrusion of the lid, like that seen in ordinary tarsal tumour. Without their removal, it could not be expected that any permanent improvement could take place. A great number of such cases were treated at the time of my inspection, and such remedies were also employed as I have pointed out in my communication to the physicians, and which are therefore unnecessary to be specified here.

The disease which I witnessed in Tipperary, I believe to be a modified form of that denominated Egyptian Ophthalmia; which I have seen, upon a large scale, at Cairo, and in other parts of the Levant; and which committed such ravages in the British army at the time of, and subsequent to, its occupation of Egypt in 1803. It still exists among our troops; and a number of soldiers, both at home and in the colonies, annually lose their sight from it. It has also lingered in particular regiments for years, notwithstanding every effort made to eradicate it, and such regiments having frequently changed climates. In gonorrhœal Ophthalmia, we see it in its worst form in Europe. It used formerly to spread in public schools, particularly Charter-houses; and it has several times appeared in the country parts of Ireland, and extended among the people not then subject to any particular privation, and apparently in previous good health. So long ago as 1701, an epidemic of this nature broke out near Castletowndelvin, in the county Westmeath, by which vast numbers lost their eye-sight.[1]

This Ophthalmia is manifestly contagious, as much so as fever, dysentery, cholera, or any other established contagious or infectious disease,

[1] I became aware of this fact in searching through the papers and manuscripts of Sir Thomas Molyneux, whose Memoirs I published in the *Dublin University Magazine* for 1841-2. "From the effect produced, and the numbers who were attacked together, with the time of year at which its attack was most violent, we have little doubt on our minds that it was some virulent inflammatory epidemic, some form of Ophthalmia, and not improbably that known under the name of Egyptian. The paper to which we refer is a list of 'Queries proposed by Dr. T. Molyneux, to John Hill, curate of Castletowndelvin, in the county of Westmeath, concerning the extraordinary distemper that took away the sight of many in that parish.' The answers to this set of questions form a most interesting statistical document, as the name of each person is given, their age, sex, and the exact effect on the sight, whether total loss of vision of one or both eyes, and the whole number who were affected, etc."—*Dublin University Magazine* for December 1841, vol. xviii, p. 753. I have introduced this extract, because I have not access to the original document at present; and, as it is among the family papers, some time might elapse before I could refer to it.

arising from some peculiar state of the atmosphere acting on those who happen at the time to be good recipients for its seeds. Or it may be propagated by direct contact of the matter or discharge from one person to another; and in this mode it is supposed that the nurses and ward-maids of the Poor-Law establishments contracted it. An impaired state of the constitution; broken down health and spirits; sudden alteration in diet; crowding together, particularly at night-time, in large masses; and the want of pure air and proper exercise, have, I think, materially conduced to spread the epidemic in the Tipperary Union. At the same time it must be remarked, that very many apparently healthy children have contracted the disease, and that, in several instances, it was brought into the workhouse by persons from the neighbouring country parts, who at the moment laboured under the affection. When once this disease takes root in a school, barrack, jail, or workhouse, it is always difficult to eradicate it; and, therefore, it behoved me to make known to the guardians, and the Poor-Law authorities, that, under the most favourable circumstances, and among persons previously healthy, even in the better ranks of life, it requires a great length of time, and the most watchful care, to get rid of its effects. Relapses are always of frequent occurrence in Ophthalmia; and, perhaps, from some cause arising out of the peculiar circumstances of the recent calamitous condition of this country, relapses were one of the most marked characteristics of the late epidemic of fever. If the British soldier, well fed, well clothed, accustomed to cleanliness, under strict discipline, previously in rude health, and supplied, not only with prompt medical assistance, but all the comforts and appliances of a military hospital, suffers for months from protracted Ophthalmia, and occasionally loses his eye-sight, how little need we wonder at the ravages committed by it among the miserable Irish peasant children.

The effects of the Ophthalmia may be gleaned from my letter to the Tipperary physicians; but upon the peculiar condition of the conjunctiva, technically denominated "granular lid", I may remark, that it is one of the most frequent sources of blindness among the lower orders in this kingdom, and is one of the most intractable diseases we have to treat. Whether it arises from the humidity of the climate, or the dirty habits and impoverished condition of the poor, it is not easy to determine; but I think more instances of it are to be found in Ireland than in any other country in Europe. It is also one of the causes of entropion, an affection of which there are more cases in Ireland, in proportion to its population, than can, I think, be found elsewhere.[1]

Of the 340 cases which I examined in the Ophthalmic Hospital, at Tipperary, I find, by referring to my notes, made upon the 12th of August, that sixteen persons, ten males, and six females, had irrecoverably lost both eyes, and that in two more they were on the point of being lost; thirty-two persons, twenty-three males, and nine females, had each lost one eye. In thirty-three cases, sixteen males, and seventeen females, one eye had been blemished (generally from dense leucoma, or cicatrix of the cornea, with synechia anterior), so as to impair, but

[1] Out of 512 operations performed at St. Mark's Ophthalmic Hospital during the last three years, 62 were for entropion and trichiasis.

not altogether destroy, vision; and in six cases, three males, and three females, both eyes were in a similar condition;—eighty-seven in all of those submitted to my inspection, where one, or both eyes, had suffered to a greater or less extent. I saw, however, some other cases, in an advanced stage of the disease, where mischief must inevitably have ensued since. Whether these eighty-seven are the entire number of persons, out of the 2068 treated, in whom complete, or partial loss of vision has occurred, I have had no means of judging, as some children had been removed by their parents during the spring; but, if they are, I do not think the number at all remarkable. We all know, that in some instances of violent inflammation of the eyes, even under the most favourable circumstances, it is not possible by art to preserve the integrity of the organ; and twenty cases of total loss of both eyes, or 1 in every 103, is, I think, rather a favourable result. Will medical statistics afford a more favourable? Do 102 cases out of every 103 of inflammation of the lungs, pneumonia or bronchitis; or of peritonitis, etc., etc., recover? Of those persons, where both eyes are, for the present, deprived of sight, but not irrecoverably lost, or disorganized, several may, in process of time, have operations performed with a fair hope of obtaining a moderately useful vision; but this will much depend on the improvement of their general health, and their being removed to a more genial atmosphere.

In addition to the foregoing statistics, the materials for which were collected by myself, the assistant-physician informed me that one hundred and forty-three adults had suffered from Ophthalmia since October 1849; they were chiefly delicate females, and some of the ward-maids and attendants. I have also been informed that, previous to the 29th of October 1849, twelve people, eight males, and four females, were absolutely blind; but they did not come under my inspection.

There prevailed an opinion among the officials, both in Tipperary and at Athlone, that in several cases the Ophthalmia had been induced by malingering; the boys wishing to be freed from school, and to get a better class of food. But, upon strict inquiry, and cross-examining the persons who were said to have first propagated the report, I did not find it borne out by their answers. A few cases of it may have occurred; but it certainly did not prevail to any extent. The means by which the boys in the Athlone Union were accused of propagating the disease—washing the eyes with urine—is, I know, a popular "cure for sore eyes" among the lower order of Irish, particularly in Connaught.

The great bulk of the patients in the Ophthalmic Hospital having contracted the disease in the male and female schools of the union, I next inspected these establishments, and fully reported to the Commissioners thereon; pointing out what I considered defects, and suggesting such improvements as the nature of the buildings admitted. Both the boys' and girls' schools are situated in the uncleanly, ill-sewered, and unhealthy town of Tipperary, which in 1841 contained 7370 inhabitants, and the average proportionate mortality for ten years was, as far as the records of the last census afforded the means of approaching the truth, 1 in 30·8. These establishments had been private residences; the rooms and out-offices belonging to which, together with some additional

buildings recently erected, were converted into schools: but taken as a whole they were, in a sanitary point of view, inapplicable to the purpose. In the boys' school, in Nelson Street, there were 107 children at the time of my visit; but as many as 370 had been located in this establishment shortly before. There was a manifest deficiency of space for exercise-ground for the children. This is an error, not only in a moral but in an economical point of view; for the guardians may rest assured that if a single acre of green-field, properly supplied with a gymnasium, and other suitable means for taking active exercise, were provided in the immediate vicinity of the town (at a cost probably of two or three pounds per annum), wherein the boys and girls of the workhouse schools could play daily, the males at one time, and the females at another, it would save them a large amount of expenditure in hospitals, medicine, and medical attendance. If the children of the rich, in our upper-class schools, require this, how much more do those poor, dispirited, and emaciated creatures, congregated together in masses, and deprived, by their unhappy circumstances, of the sympathy of their natural guardians, demand some such means of healthful recreation. The school hours are from ten to three. Three times a week, when the weather permits, the children are taken out for a walk upon the roads. The food and clothing, supplied to this establishment, were both very good; but neither can supply the want of pure air and active exercise. The chief dormitories were long, thatched apartments, each sixty feet by fifteen, and the walls eight feet high; but the ridge poles of the roofs were sixteen feet from the floor. The ventilation, heretofore provided in these apartments, was, to my mind, totally inadequate; but, shortly before the date of my visit, it had been greatly improved, by means of apertures, made in the side walls, and in the roof. As many as eighty boys have usually slept in each of these apartments; but I was informed that as many as one hundred and twenty-five had slept in a single room of the dimensions I have described. Upon inquiry, the schoolmaster informed me, that "the Ophthalmia *almost invariably attacked the children during the night time, and chiefly those who slept in these very apartments*". In the front house in Nelson Street, which was originally a private dwelling, and in which the apartments were consequently smaller, and much better constructed, with respect to warmth and ventilation, than those I have just described, I was informed that, "there had been but few cases of Ophthalmia". From the 15th of May to the 15th of August, one hundred and ten boys were seized with the epidemic in this school, and removed to the Ophthalmic Hospital.

The means provided for the boys to wash themselves were, it appeared to me, quite inadequate, not merely for cleanliness, but for the maintenance of health; but, as far as I have had an opportunity of judging, the appliances for ablution in the Irish workhouses generally are defective. I need scarcely wonder at the guardians and inspectors permitting the peasant boys in the Irish Auxiliary Workhouses to wash at a pump or with a bucket in the open air in all weathers, when I remember what was the condition of things not many years ago, at one of the largest schools for the gentry in this country—one too on "Royal Foundation". There were no means for washing provided in the large dwelling-house wherein the boys slept; but half-dressed, they scampered every morn-

ing, winter and summer, across an open court or play ground, to an out office, which had recently been a stable, and the floor of which was still paved. There, from fifty to sixty young gentlemen rushed at a large trough, like a manger, in which there were eight or ten basins, and struggled for a wash, and afterwards for the first, or at least a moderately dry wipe with about as many towels. In the Athlone Auxiliary Workhouse, matters were in a still worse condition in this respect, 354 girls and 38 little boys being submitted to the process of ablution, or more properly speaking, of *wetting*, upon an exposed and elevated part of the yard, each morning, on their way from the breakfast-room to the school-room. Every medical practitioner, every mother, every old woman, knows full well what the effects of such sudden chills are in producing inflammations. The children in our workhouse schools are, I believe, very well taught the national system of education, and it is highly gratifying to witness the order, discipline, and regularity which prevails there; but if, besides the marching and counter-marching which they are drilled into (all most necessary I admit), habits of cleanliness and comfort in the matter of ablution were also instilled into these children, would it not forward the process of civilisation in Ireland?

The girls' schools at Bank Place, also in the town of Tipperary, and then the chief source of the epidemic, I inspected and reported on; but in the previous statement and observations, will be found the substance of my report, so far as concerns the objects of this communication, or as the medical profession need be acquainted with. At Grenane, about a mile from the town, there is another girls' school, containing, at the time of my visit, 331 girls, clean, healthy, and in good spirits. There was a plentiful supply of water, the night-soil cart was removed daily, the dormitories, school-rooms, and the entire establishment, were in the highest order. Originally, when the disease first appeared, many cases of Ophthalmia were sent to hospital from this school, but latterly, it had almost disappeared there. The mistress stated, that the disease chiefly attacked the recently admitted children, but that, in several instances, the new comers presented symptoms of the affection on their admission.

The following is the letter which I addressed to the medical attendants of the Tipperary Workhouse, upon the 16th of August.

"Gentlemen,—Pending the presentation of my Report to the Poor-Law Commissioners, respecting the cases of Ophthalmia which I examined upon Monday last, the 12th instant, in the Auxiliary Workhouses of Tipperary, I beg leave to put you in possession of my views on the treatment which I think it would now be most advisable to adopt.

"Upon the first seizure, if the previous general health of the patient is such as might warrant it, I would strongly recommend slight local depletion, by means of a leech or two applied over the edge of the malar bone, immediately beneath the external angle of the eye, and repeated next day, if the strength of the patient permit it, or if the inflammatory action continue unabated. This refers to young children, the most frequent subjects of the disease. The number of leeches must be regulated by the age and strength of the patient. In adults, cupping the temple and drawing therefrom three or four ounces of blood, will, I think, be

found beneficial in mitigating the severity of the original symptoms. Where there is much swelling of the lids, cold applications are generally found most grateful. I highly approve of your judicious use of the nitrate of silver; but I would suggest the propriety of keeping a solution of that medicine in a separate vessel in each ward, and having it so managed as to exclude as much light as possible; for the dark precipitate thrown down by decomposition, gives, when applied to the eye, unnecessary pain, and it is far from beneficial. I see no objection to your employing a solution of this medicine as strong as six or eight grains to the ounce, in the very early stage, when the conjunctivæ of the lids becomes villous and pulpy, and pours out in great quantity a thin mucopurulent discharge, and when that covering the globe is raised up into a serous chemosis. But as soon as ever the symptoms of intense inflammation subside, I would lessen the strength to about three grains, or even one grain to the ounce. In cases, however, where you think it advisable to employ the weak solution, it ought, I conceive, to be used more frequently, say three times in the twenty-four hours. The nurses should be taught how to apply this remedy.[1]

"With the exception of some mild aperient, given at the commencement of the attack, in those cases where the tongue is white, or loaded, I do not think that much benefit is to be derived from purging the class of patients you have to deal with; neither do I see much good likely to accrue from lowering them by means of tartar emetic, the patients which will bear such being evidently the exceptions. If a warm bath can be easily obtained, I think good will ensue from its use; and, in the treatment of the subsequent chronic stage, I am sure you will find it very desirable; but it must be properly managed to be effectual.

"As soon as local depletion has been had recourse to, the bowels freed, the bath used, and the solution of nitrate of silver dropped into the eye, I should strongly advise you to administer cinchona bark, and give it liberally, particularly during the subacute stage.[2] The decoction, with a little of the syrup, will, I think, be the most easily obtained preparation, and the most applicable to a large institution.

"As far as the patients are willing to take it, I would recommend

[1] Wherever in this Report recommendations are made, or suggestions offered, upon subjects of apparently trivial import, it is because some good reason for my doing so presented itself at the moment. It must be remembered, that the nurses and ward-maids of an Auxiliary Workhouse Hospital are themselves pauper inmates, generally very ignorant, and totally unacquainted with those matters familiar to the usual nurses of general hospitals.

[2] It has been asserted, with what degree of propriety the profession are to judge; that as inflammation of the conjunctiva, commonly called purulent Ophthalmia, in its simple and uncomplicated form, proceeds through its different stages to perfect recovery, unaided by any medical interference, we should refrain resolutely from any officious meddling with the disease, etc. How far this line of practice is applicable to inflammations in other organs in their mild uncomplicated form,—simple inflammation of the mucous membrane of the lungs, throat, bowels, or the genito-urinary organs, for instance,—those who are extensively engaged in practice are alone capable of forming an opinion. Every one who visits the continental hospitals has an opportunity of judging of the positive results of the *expectant treatment* in inflammatory diseases. Not long since, the profession witnessed the decay of a periodical wherein such doctrines were broached; and their promulgation now only proves that some persons have outlived all faith either in medicine or themselves.

plenty of nutritious food, good wholesome bread and milk, or stirabout and milk, as well as some broth containing fresh vegetables, during the day. In the treatment of these cases now in hospital, as well as in the regulation of the dietery of the schools where the disease has been acquired, I would suggest to you the propriety of varying the description of food from time to time. Properly cooked potatoes, instead of the usual meal of brown bread, would, I am sure, be considered a luxury, and tend to keep the children in good health. Although the patients in the Ophthalmic Hospital may, from its sweetness, prefer tea to milk, I would not recommend you to accede to their wishes generally, but I think the use of cocoa, made of a proper strength, and given with an equal proportion of warm milk, and some sugar, would be both palateable and nutritious.

"From what I saw of the disease, and from the account which you have given me, it is manifest that it is, in the first instance, amenable to treatment; few cases having occurred in which the cornea sloughed, or the eye burst, through the violence of the primary attack. The great majority of cases in which permanent or irreparable mischief has occurred, seem to be those in which the cornea ulcerated, and the iris protruded, subsequently to the original attack, producing either staphyloma, or extensive leucoma, with adhesion of the iris to the cornea. The treatment of such ulceration will, no doubt, greatly depend on the appearances presented in each individual case; but, as such affections are nearly always induced by some constitutional derangement, such other means of strengthening the system as circumstances will permit, must also be employed. Where the patient is much broken down, and the disease is in a chronic stage, I beg to suggest the plentiful use of cod-liver oil, of which medicine a large supply should be at once procured, and a table-spoonful given to each child two or three times a day. I saw, I am sure, fifty cases, among those under your care, which would be greatly benefited by the use of this remedy. It is most applicable to those cases in which there is much emaciation, paleness, a cold clammy skin, and large flabby granulations, and sometimes transparent ulcers of the cornea.

"As the great tendency of this disease is to cause exuberant growth of the conjunctiva, presenting various kinds of granulations, which form the sequelæ of the affection, I would advise you in every instance, as soon as the swelling of the upper lid has subsided, and the more urgent symptoms have passed away, to evert the lid in order to examine the state of its conjunctival lining, and to apply the solution of nitrate of silver directly to that part, and then, by keeping the lid thus retained for a few seconds, until the caustic has acted upon the swollen villous surface of the membrane, granulations may be prevented from forming.[1]

[1] To evert the upper eyelids, in order carefully to examine the diseased conjunctiva, and to apply suitable remedies, in some hundred cases once a day, or even every second day, in addition to the ordinary attendance necessary upon a large workhouse, requires an amount of time which few medical men could give, or the Board of Guardians would be willing to pay for. Still it was my duty to point out what I conceived to be necessary; but, at the same time, I recommended the Poor-law Commissioners to advise the guardians to furnish additional medical attendance.

" With respect to the local treatment of the ulcers,—several of which were transparent, as if a piece had been chipped out of the cornea,—I would recommend you to touch them with a solution of nitrate of silver, of the strength of about four grains to the ounce, applied with a fine camel-hair pencil. These ulcers seem to me to penetrate the cornea from want of power, in the neighbouring parts and the constitution generally, to repair the mischief, few, if any of them, presenting the usual vascular connexion with the adjoining conjunctiva and sclerotic, which is commonly set up to restore the breach. I saw several instances in which the cornea had just been ruptured, and a small portion of the iris protruded. These cases, if allowed to proceed unchecked, will inevitably go on from bad to worse. The aperture in the cornea enlarges, and a considerable portion of the iris protrudes, and the final result is either partial or complete staphyloma, or an extensive leucoma, the whole or a large portion of the pupil becoming attached to the cicatrix. In such cases, I would recommend that, as soon as you perceive that the ulcer has penetrated, you should touch the knuckle of protruding iris with a very fine brush, wet with a weak solution of nitrate of silver, and immediately afterwards drop into the eye a solution of atropine, of the strength of two grains to one drachm of distilled water.[1] The eyelids should then be fastened down with narrow strips of adhesive plaster, and a piece of fine lint plentifully smeared with a moistened extract of belladonna should be applied over the eye, and retained in this position by a light bandage. From the crowds at present in your hospital, and the liability of cases so circumstanced meeting with any accident, I would recommend to have them confined to bed. The eye should not be opened for the next four days; but, as the lint becomes soiled and stiff with the discharge, it may be changed as often as necessary, and fresh belladonna applied round the orbit.

" In cases where ectropeon of the upper lid has taken place during the violence of the original inflammation, great care should be taken to restore the lid to its natural position, as it sometimes remains in a most distressing condition for weeks, and even months, of which, at present, you have some examples in the hospital.

" The foregoing observations refer to the more active forms of the

[1] The treatment recommended above I published in my Ophthalmic Report for 1848 (see *Dublin Quarterly Journal*, vol. v, p. 489). Since then, I have had many opportunities of testing its value; and the pupils in attendance at the Ophthalmic Hospital have frequently witnessed its efficiency during the last few months. To state that belladonna or its alkaloid will not cause a knuckle of iris protruding through a recently opened ulcer or rent in the cornea to retract, and the pupil to expand, exhibits a want of practical knowledge of ophthalmic surgery. It is to be regretted, I think, that atropine, one of the most powerful salts, and one of the most efficacious remedies with which we are now acquainted,—far more cleanly and much more certain than belladonna,—has been omitted in the recently published Dublin Pharmacopœia. Since I first brought the use of this remedy under the special notice of the profession in this country, I have found that, in some cases, a single drop of a solution of the strength of two grains to a drachm, consequently about the thirtieth part of a grain of atropine, will, if dropped upon the conjunctiva of the lower lid, be perceived, by its bitter taste in the mouth, in a quarter or half-an-hour after its application. Where it has been necessary to use this remedy for some length of time, as in cases of contracted pupil, or central cataract, etc., an unpleasant dryness of the fauces is experienced, in addition to the usual bitter taste. Isinglass plaster, made on firm sarcenet, is preferable to the common sticking-plaster for fastening down the eyelids.

disease. I have now to give you my opinion of the chronic cases, which form the great majority of those submitted to my inspection. In the observations which it is my duty to make, and the recommendations which I suggest for the removal of those errors which it appears to me have been committed, and still exist in the general management of your ophthalmic hospital, I beg to state that I am well aware that it is not within your power to rectify them. Their removal I will strongly impress on the Commissioners, but, at the same time, it is proper you should always bear them in your recollection. The wards of the hospital are much too low, and far too many patients are crowded into them. The ventilation is both irregular and inadequate. The clothing of a great number of the children is insufficient. During the approaching cold weather, some means for heating the wards must be procured, and the unglazed windows must, in inclement weather, be properly secured. Cleanliness is not sufficiently attended to; three sponges are not enough for a ward containing nearly one hundred patients; there should be at least a dozen sponges, and the elder children should be shown how to use them themselves, and compelled to do so several times a day.[1] For the recent cases, where the discharge is believed to be infectious, I would recommended the use of small portions of tow instead of sponges, as a fresh supply of the former could be had daily at a very small expense. I do not think three night buckets sufficient for the number of patients in each ward; there ought to be at least five or six. The removal of excrementitious matter, and the cleanliness of the privy, has not been sufficiently attended to; you should insist on having the ordure cart removed daily. At the time of my inspection, the bedding, particularly the sheets, were not so clean, and consequently not so healthy, as you are aware they ought to be.

"I will strongly urge upon the Commissioners the necessity of immediately procuring some country place to which the ophthalmic patients may be removed, and where they will have a constant supply of fresh air, and be able to take open air exercise (if possible, in a green field, instead of a confined yard); without which means, neither medicine nor any effort on your part will prove available in a great number of cases.

"I would suggest the advantage, both to yourselves and the patients under your care, of making some classification of them according to the severity of their symptoms, and thus prepare the way for lessening the number of children in the establishment. I saw several patients with slightly granular lids and some mucous discharge from the eyes, but without any active inflammation of the conjunctiva of the globe or any intolerance of light, who might at once be removed, if a proper place were provided for them. As the disease is not likely to be infectious in that state, they might be sent to the parent workhouse or back to school, provided they were not confined, nor employed in learning five or six hours a day, which I find is the time the children have been occupied in the schools where the disease was originally contracted. In treating those mild forms of chronic Ophthalmia, I think you will find it bene-

[1] I think we are in the habit of allowing patients with inflammatory affections of the eyes to *slop* too much, either by steeping, or keeping on a wet rag for hours together. I am convinced that much greater benefit will be derived by fomenting the eye properly, or applying a cold lotion by means of a fold or two of fine linen for a quarter of an hour at a time, and then carefully drying the part.

ficial to use the wine of opium made without aromatics, and mixed with an equal quantity of laurel water, dropped into the eyes once a day.[1]

"Chronic Ophthalmia, kept up by a granular condition of the conjunctiva of the lids, chiefly the upper, is now what you have principally to treat. By making the following classification, and by getting a registry constructed in accordance with it, you will, I think, be able to get through your work more easily. If, moreover, each class could be kept in separate wards, it would, I think, hasten their cure. Until another house is provided, the present large wards might be divided by temporary partitions.

"Class I. All the recent cases, before they have passed into the chronic form. They should, if possible, be at the top of the house.[2]

"Class II. The totally and irrecoverably blind. These had better, I think, be separated from the rest of the patients.

"Class III. All those with ulcers of the cornea, protrusions of the iris, or staphyloma not producing blindness. In recent cases of staphyloma of the cornea projecting through the lids, and causing much irritation, I would recommend you to tap the protruding part with a flat needle every now and then, so as to lessen its bulk and remove the pressure made by the contained fluid. A light pad, made to exercise some degree of pressure on the eye, while this mode of treatment is being adopted, I have known to prove beneficial. In all cases of recent adhesion between the cornea and iris, I would recommend the continued dilatation of the pupil by means of atropine or belladonna. In cases where complete closure of the pupil exists, but in whom the operation of artificial pupil may hereafter be resorted to with some hope of success, equal care, both to improve the general health and to remove any disease existing in the eyelids, should be taken as in those already described.

"The first and third classes should be visited daily, the second but every third day.

"Class IV. With small hard granulations, generally distinct and separate. These I would recommend to be touched in the manner I pointed out to you every second day, with sulphate of copper; they need not be examined upon the intermediate days. The constitutional treatment, by means of bark or cod-liver oil, should be employed in several of these. Where there is much intolerance of light, irritation of the membrane of the external nares, and swelling of the upper lip, with other strumous manifestations, I would recommend you to use, in connexion with the bark, very minute doses of the oxymuriate of mercury, say the sixteenth to the eighth of a grain. Such cases will also be benefited by the application of a blister to the vertex; but blistering, in the generality of cases, such as those I witnessed in your ophthalmic hospital, will not, in my opinion, prove beneficial. I do not think the usual bitter infusions, or even hydriodate of potash, improve such cases, or indeed many cases of ophthalmia in young persons; but some benefit may be derived from the use of the syrup of iodide of iron, particularly in very young children.

[1] The removal of the hot spices from the wine of opium is, I find from long experience, a great improvement, when this tincture is used as a collyrium. This formula has, I am glad to find, been adopted by the compilers of our new National Pharmacopœia.

[1] The treatment of these recent cases has been described in the commencement of this letter.

"Class v. With large distinct granulations, such as those you saw me remove, and which principally congregate at the sulcus, formed by the reflection of the conjunctiva from the upper lid to the globe. These cases should be seen and their lids everted daily, and as many of the granulations as possible cut off with a curved scissars. The inner surface of the lids may occasionally be scarified slightly, and the bleeding, which will prove rather beneficial, should be encouraged by fomentation with warm water. Besides the removal of these large granulations, some local astringent should now and then be employed as the granulations disappear, such as the sulphate of copper, solution of nitrate of silver, or the acetate of lead, which latter I shall presently allude to. The constitutional treatment of such cases is even more necessary than in the foregoing class. From week to week, cases of this and the 4th and 6th classes may be removed into the 7th class, which will not require such constant attendance.

"Class vi. Are those in which the conjunctiva presents an uniform granular condition, the surface of the granulations, however, being tolerably smooth, although they may be separated by passing a probe between large packets of them. They are generally less florid than in the preceding class, and the patients are always run down in health. They will require an energetic constitutional treatment, with as much animal food as the dietary of the institution will permit. Ulceration of the cornea exists in a great number of these cases, presenting the appearance of an abrasion of its surface without any surrounding greyness. The local treatment which I think you will find most beneficial in these cases, is to unload the deeply congested purple granulations by very light scarifications, and, in a day or so afterwards, to apply finely levigated acetate of lead. For this purpose the lids should be everted, their internal surface gently dried, and the lead applied either with the top of the finger, or a camel's-hair pencil, so as to completely cover over the exposed surface. The lid should be still held firmly everted for at least a minute, during which time the lead will have dissolved, and the granulations will have changed colour very considerably, assuming the hue of an unripe mulberry. The parts should then be washed free of the application with a little clean water, either by means of a syringe, or a sponge. It will not be necessary to examine these lids again for three days. As there is an opinion that lead is deposited, and leaves a permanent stain, where there is any breach of surface in the cornea, perhaps it would be as well to confine this application to the cases where ulceration does not exist, using the solution of nitrate of silver, applied after the same manner in those where ulceration is present. After one or two applications, the lead will form a sort of enamel, of a whitish colour, and of great smoothness, over the surface of the lid. As long as this is present, it should not be interfered with, nor the remedy re-applied, except to such spots as it has not taken effect upon.[1]

[1] This mode of applying finely powdered acetate of lead to the hypertrophied villi of the palpebral mucous membrane has been highly recommended by Dr. Buys, a Belgian military; surgeon and the results of his observations have been published at length in Dr. Cunier's excellent journal, the *Annales d'Oculistique*. A form of Ophthalmia, very similar to that now prevailing in the Irish workhouses, has recently spread among the troops in Belgium, and also extended through the public institutions, and among the lower orders in that country; on which several valuable reports have been published in the periodical alluded to. The action of powdered

"CLASS VII. Are those with simple uncomplicated chronic Ophthalmia.

"I would, as soon as proper accommodation and other means are supplied by the Poor Law guardians, or the Commissioners, completely separate all those who are totally and irrecoverably blind from the rest of the patients. As soon, also, as possible, some description of amusement should be procured for the children, who should be kept upon fine days as much as possible in the open air, or in a large airy day-ward in wet weather. Fortunately, there being so little intolerance of light in the great majority of the cases your hospital presents, the children will always be able to do this. I have been very much struck with the circumstance of there being so little development of scrofula in the children affected with the present epidemic Ophthalmia in Tipperary; only two or three instances of enlargement of the glands of the neck presenting in 350 patients; a fact of some interest, as tending to show the purely epidemic nature of the disease, and to distinguish it, even in the chronic form, from that generally denominated Scrofulous Ophthalmia. It also appeared to me remarkable that only one or two instances of Pannus, or vascular cornea, such as that which so frequently occurs as the consequence of Ophthalmia in the army, were to be seen in the vast number of cases under your care, and in several of which sufficient time had elapsed to permit of the formation of such appearance. This circumstance, I think, tends to show the asthenic nature of the disease you have had to treat, and the broken-down class of subjects in which it has appeared. Extreme coldness of the end of the nose is a symptom which I have long observed to be attendant on chronic Ophthalmia with granular lids, in debilitated patients, and it was to be observed very frequently among the children in your Ophthalmic Hospital.[1] To such cases the cod-liver oil is peculiarly applicable. The total absence of all other ophthalmic diseases, except the purulent Ophthalmia, and its consequences, was most remarkable; and the circumstance is fortunate, as, had the internal structures of the eye partaken in the inflammatory action, the disease would have been less under control, and the usual remedies, mercury in particular, inapplicable to the class of patients you have had to deal with. Of pustular Ophthalmia, so common at present among children and young persons, I did not see a single instance either in the hospital, or among the numerous pupils, males and females, whom I saw in the schools.

acetate of lead is not the same as that of the liquor plumbi, even in the undiluted state. Even though it were, the mode of applying it would produce a different result. Every one engaged in Ophthalmic practice knows full well that any fluid caustic, or astringent, simply dropped into the eye with the palpebræ, generally at the moment spasmodically contracted, exercises but little influence on the inner surface of the upper lid. To prove effectual, the substance, fluid or solid, must be applied to the membrane itself.

[1] Coldness of the extremity of the nose is an attendant symptom of chronic Ophthalmia; just as much as congestion of it is characteristic of affections of the choroid or the internal structures of the eye; or swelling, redness, and an eczematous eruption, of the external nares, the septum, and the upper lip, is a constant attendant on certain forms of scrofulous Ophthalmia. To deny such, exhibits either defective vision, or undeveloped powers of observation.

In several cases at Tipperary, enlargement of the pre-auricular gland—*Bubon-pre-Auriculaire*, first noticed by Dr. Hairion, of Louvain, as an attendant symptom in gonorrhœal Ophthalmia, was observed. But, as we already stated elsewhere, it is common to other forms of ophthalmic inflammation besides the specific.

"As the yard of the present establishment is so confined, I would strongly suggest the propriety of sending forty or fifty patients, under the superintendence of a proper care-taker, to a little distance into the country every day. Two hours of freedom in some of the neighbouring green-fields daily would be of great benefit to the poor children cooped up within the narrow limits of the hospital, and would be an eventual saving to the guardians and rate-payers in the items of medicine, medical attendance, hospitals, and the subsequent permanent support of a number of blind people. There are several patients in your hospital whose sight might be saved if they were completely removed from the establishment, and placed under the care of their friends in the country. But this is a matter on which I do not possess sufficient information to be able to suggest any decided step. If, upon the breaking up of your present establishment, and the removal of the patients to a more healthy locality, you could by any means get rid of the fleas which swarm in the beds, and literally cover the sheets with minute specks of blood, it would, I think, tend to improve the health, and minister to the comforts of the miserable patients you have to treat.

"As it will be necessary to examine each individual case of the 350 now under treatment, to evert the eyelids and apply the necessary remedies, as well as prescribe medicine, and regulate the dietary, once in three days at least, and in some cases daily, I will recommend the Commissioners to afford you additional medical assistance as soon as possible. Until, however, some more healthy locality, with sufficient ground for enabling the children to take exercise, is supplied, I do not think any general improvement will take place in those under your care."

Dublin, 16th August, 1850.

OPHTHALMIA IN THE ATHLONE UNION.

In accordance with the directions of the Poor-Law Commissioners, I proceeded to Athlone upon the 23rd of August, and, in company with the physician and the master of the workhouse, I visited the different localities where I was informed that patients labouring under Ophthalmia existed; and also carefully inspected the schools, where the disease is said to have originated. As the remarks, which I thought it my duty to make upon this disease, its apparent cause, and its treatment in the Tipperary Union, were equally applicable to the circumstances of the Athlone Workhouse, I did not consider it necessary to extend my report upon the latter to the same length as the former, but contented myself with pointing out what I considered the most striking defects in each section of the auxiliary workhouses; and I also "suggested to the Commissioners the expediency of furnishing copies to the officials at Athlone, both of my letter to the medical attendants of the Tipperary Union, and also of my general report" thereon. I pointed out, in as strong terms as language at the moment supplied me with, what I considered to be manifest defects in the warmth, ventilation, cleanliness, mode of washing, and the general accommodation of the several establishments through which I was conducted. It appears, from the public prints, that the Board of Guardians at Athlone have been put in possession of my opinions and suggestions; to what extent they have availed themselves of these I know not, and, except for the sake of humanity and the credit of my countrymen, it concerns me not to inquire.

At the time of my visit, the disease or its effects were to be observed

in the girls' school, in a temporary hospital, in the boys' school, and in the Infirmary, and the Fever Hospital, these latter being within the precincts of the parent workhouse. The first of these establishments, denominated No. 1 Auxiliary Workhouse, had formerly been a private residence; it contained 354 females under fifteen years of age, and 38 males under five, who were in an infant school attached thereto. Upon inspection, I found that numbers of the children here laboured under the Ophthalmia in a chronic stage; some, the very young children particularly, were just as severely affected as those in the hospital at Tipperary, the same peculiar effects exhibiting themselves, in exuberant growths of the lining membrane of the lids, etc.; but ulceration was not so common. Upon these effects and the best method of treating them, I consulted with the medical attendant, Dr. O'Connell, who accompanied me in my visit. The matron of the establishment had been supplied with a bottle containing a solution of lunar caustic, and she seemed to have been well instructed in the method of applying it; but I believe it will be conceded, that, in order to arrest the progress of this disease, and to counteract its effects in a chronic stage, it is absolutely necessary that a medical inspection of a great number of the children of this or any other school, when it prevails, should be made every five or six days at least, and their eyelids everted, in order carefully to examine the state of the conjunctiva, and to employ such remedies as may be deemed advisable at the time. Those labouring under severe chronic Ophthalmia with granular lids, I recommended to be separated from the others. Several of the cases here seemed to me to require active constitutional treatment, in order to correct the tendency to relapse, and to assist in eradicating the disease from the establishment.

Generally speaking, the girls in the Athlone School appeared to be much more healthy than those either in the school at Bank Place, or the Ophthalmic Hospital of Tipperary. Moreover, very many of them were of a somewhat different race, having dark eyes and complexions, and consequently presenting fewer instances of the deleterious effects of ocular disease.

All forms of external Ophthalmia seem to affect light-haired people with blue or grey eyes and delicate skin, and particularly those with what are termed sandy complexions, more than those with dark complexions and brown or hazel eyes; and such diseases likewise produce, in the former, more violent symptoms. Of 1659 cases of external inflammation, including conjunctivitis in different forms, pustular, catarrhopustular, strumous, and purulent Ophthalmia, etc., registered at St. Mark's Hospital during the last three years, and in which the colours of the irides were accurately noted, 1155 were light-coloured, grey or blue; and 504 brown or hazel; being in the proportion of about 9 to 4. It must, however, be borne in mind, that light-coloured eyes, the blue-grey in particular, predominate in this country. The most marked difference occurred in the cases of pustular Ophthalmia, where there were 272 light, and 152 dark coloured; and in strumous Ophthalmia, generally marked by intolerance of light, etc., there were 267 light-coloured, and only 107 brown or hazel eyes.[1]

Forty-nine children in this school had, at the time I visited it,

[1] See Fourth Report of the St. Mark's Ophthalmic Hospital and Dispensary for Diseases of the Eye and Ear. Dublin: Alex. Thom. 1850.

suffered severely from the effects of the Ophthalmia, but in only two instances had both eyes been irrecoverably lost; two more had both eyes seriously injured, but in these latter, vision may in time be restored by operation; twenty had each lost one eye; twenty-three had each one eye seriously injured; and two had slight opacity of the cornea. In passing, however, through the school, I observed very many children with chronic Ophthalmia and a villous or granular state of the lids. It would appear that the disease had been, in the first instance, even more violent than in Tipperary; but, perhaps from the difference of race, the better state of the general constitution of the children, and the more healthful situation of the school, the subsequent consequences—chiefly intractable ulceration, kept up by an impoverished state of the constitution—were not to be observed in No. 1 Auxiliary Workhouse in Athlone: but then it must be observed, that some of the worst cases had been removed to the infirmary of the parent workhouse. The epidemic appeared to be on the decline, only two cases having occurred there during the three days previous to my visit. I understand that the disease broke out among the paupers in the Athlone Union, in April 1848, instances being at the same time observed in the surrounding country parts, and in the town of Athlone; and that 470 cases of it had been treated in the Workhouse during the twelve months previous to last August.

Having pointed out, in my Report to the Commissioners, the defects of the various establishments at Athlone in which the disease had sprung up, or then existed, both in the dormitories and dining-rooms, and remarked upon the general management of these institutions, it is unnecessary for the purpose intended, here to recapitulate them: but, as some notice of the following circumstance has already appeared in the newspapers, I here transcribe from my notes what occurred, in the hope that the like neglect may never again be permitted. Upon inquiry as to the mode of washing the children, I was informed that the process was then going forward. Furnished with an umbrella, for it was raining at the time, I proceeded to the spot, and found two of the adult female paupers, each with a bucket of water before her, standing upon one of the highest and most exposed portions of the yard, and which commanded an extensive view of the adjoining river Shannon, and the damp, swampy ground beyond and around it. The children, according as they breakfasted, crept along an adjoining wall for shelter on their way to the schoolroom, which was at a considerable distance; and as each child came up, one of the washerwomen laid hold of it, pulled down its dress in front and behind, and bending it over the bucket, threw some of the cold water with her hand upon the face, neck, breast, and shoulders of the little girl, and then gave her a scrub with the open hand. Sometimes the child escaped before the process was completed, and ran off with the water trickling from its hair and down its neck; in other instances, the children were dried with their own dresses. There were no towels there; and, upon inquiry, I found that but two had been supplied by the guardians for the entire establishment. The matron and the schoolmistress, who were present, and who were exceedingly intelligent, pains-taking persons, and apparently very humane, and anxious about the children, seemed quite unconscious of the deleterious effects likely to ensue from this mode of ablution and exposure of the body in the open air. I pointed out to the physician who accompanied me, the

great likelihood of such a chill producing Ophthalmia in weakly children already predisposed to it, and in an institution where it was manifestly an epidemic. The children should be washed and properly dried in some unexposed apartment, or their dormitories, immediately upon their rising in the morning, and not after breakfast.

No. 2 Auxiliary Workhouse, now used as an additional infirmary, was originally a malt-house, and is situated in a confined, damp situation, bordering the river, probably in order to facilitate the germination and fermenting process of the corn. From the construction of the building, its low vaults, narrow passages, and very scanty rooms, I conceived it to be totally incompatible with the maintenance of health in any persons confined within it. It was, moreover, in some parts exceedingly uncleanly. I suppose we must attribute to apathy and indifference,—consequent upon familiarization to scenes of misery and destitution—the circumstance that the guardians and the inhabitants of Athlone generally suffered such an establishment as this to exist. The patients in this hospital were chiefly cases of dysentery and Ophthalmia. Of the latter, there were fourteen; and of these, eleven boys, aged from 8 to 13, presenting the worst cases which I witnessed any where, miserable-looking creatures, squalid and ragged, slept on boards laid directly on a damp floor in a sort of cellar or dormitory 33 feet long, 10 broad, and 7 high, with unglazed windows facing a yard surrounded by high walls, and only 25 feet square. This inclosure was the exercise-ground for these and about twelve other boys located in the same establishment! These are defects in an institution intended for the improvement of health which, it seems to me, a medical man sent to inspect, is imperatively called on, both in justice to the inmates and to the authorities, fully to describe. Of the eleven boys in this apartment, three had lost both eyes, three had lost one eye each, and the remainder had one or both seriously injured. In such cases, medicine can be of no avail; I therefore strongly recommended that they should be removed to a more healthy locality, and that all the boys in this establishment—numbering about thirty-three—should at once be sent to some auxiliary house in the country, or as many as possible taken into the infirmary of the workhouse. In making a selection for this purpose, the curable cases alone should be removed, as it would be unfair to occupy a bed with an irrecoverably blind patient to the exclusion of one who had still an eye to lose.

I visited the boys' school at the Workhouse, and was informed that no fresh case of Ophthalmia had occurred among the children there for three weeks; several, however, had slight chronic Ophthalmia, and of seventeen whom I had subtracted from the rest as having suffered from the recent epidemic, two had lost both eyes, and seven, one each. The remainder had impaired vision in one or both; but it was stated that some of the children with blemished eyes, both here and at the girls' schools, had had Ophthalmia at their own homes, and had been received with blemished eyes. These boys did not look as healthy as the girls I have just described, and this school presented a much greater proportion of the fair complexioned. The clothing was insufficient; but the sleeping apartments of these children were clean, comfortable, airy, and in the highest order, which will, I think, account for the comparatively few cases of Ophthalmia which have occurred in this school.

In the Fever Hospital, there were several suffering from Ophthalmia in all its stages. Of twelve girls, two had irrecoverably impaired vision of the right eye; four boys had each lost one eye, and two others had extensive leucoma of one eye. Two adults had each lost both eyes. In the infirmary, there were twenty-one cases of Ophthalmia more or less severe; three of these had each lost one eye.

The epidemic seemed upon the decrease. There was but one recent case of severe purulent Ophthalmia at the time of my visit. Upon examination, the inside of the upper lid was found to be covered with an adventitious membrane of recently organized lymph, such as that which other mucous surfaces pour out in the early stage of excessive inflammation—in croup and diphtheritis particularly, and probably in dysentery also. In cases of suppuration of the eyeball, I have seen it formed over the entire surface of the chemosed conjunctiva in the space of twelve or fourteen hours, and so firm and extensive as to permit of its being taken off *en masse* with a forceps. The existence of this pseudo-membrane, particularly in the Ophthalmia of new-born infants, was pointed out some years ago by M. Chassaignac. A similar appearance has been observed in other epidemics of Ophthalmia in different parts of Europe and in Egypt, and it was very manifest in the severe Ophthalmia which recently prevailed in Belgium. I think it should be removed as soon as possible with a camel's hair pencil, and the surface then washed over with a strong solution of nitrate of silver, a practice which proves so beneficial in certain inflammations of the pharynx.

The physician agreed with me in the propriety of the treatment which I recommended, and which was nearly the same as that pointed out in my letter to the medical officers of Tipperary; viz., slight local depletion in such cases as would bear it, the use of astringents, attention to the state of the digestive organs, and then supporting the strength and improving the general health by nutritious diet, pure air, and the liberal use of tonics, particularly bark and cod-liver oil. According to my experience, a couple of leeches, applied in the neighbourhood of the affected eye in a child, is not only much more effectual in arresting the progress of the inflammation, but also much less exhausting to the patient's general strength, than a large blister placed upon the nape of the neck or between the shoulders. When blisters are applied behind the ears, or in the immediate vicinity of the affected organ, as on the side of the cheek or the temple, they cause, in young children particularly, great irritation and restlessness, and often give rise to eruptions on the face, difficult to cure. It must, however, be remarked, that where leeching is to be used in many cases, it will require a larger staff of attendants than is generally allowed for Poor-Law Hospitals. The system of purgation is too liberal in many of our public institutions. In catarrhal or muco-purulent Ophthalmia in children in this country, the tongue is, upon the first accession of the disease, generally coated with a thick, putty-coloured exudation, through which the bright red papillæ stand up prominently; and the better state of health the child has been in previously, the more marked is this symptom. Hence, the well-fed children of the middle classes more frequently present it than those of the poor. In such cases, the digestive organs demand special attention. But we frequently meet cases among the lower orders where the tongue is quite clean from the very first, nay, is

often unusually florid, and these will not be benefited by purgation. In relapses, even among the most robust children, the tongue is seldom so foul as in the original attack. Where the Ophthalmia has suddenly —as in the course of a few hours—seized a person, the tongue is seldom much loaded. In Tipperary and at Athlone, the prevailing character of the tongue in those sub-acute and chronic cases which I inspected was either pale red, or like the surface of a piece of macerated liver.

Before I conclude this report upon the Ophthalmia in Athlone, I beg leave to append the following account of a similar epidemic which prevailed in the 31st Regiment, while stationed in that garrison, for which I am indebted to my friend Dr. Massy, the Assistant-surgeon of that corps. "The regiment suffered slightly from Ophthalmia at Manchester, and also after its arrival in Dublin, where we left all our cases of Ophthalmia. We reached Athlone in July 1848, but we had also several men in the ranks with tender eyes, and these I always thought it would have been well to have separated from the rest. At head quarters we had 730 men; and two detachments, one of 90, at Roscommon, and the other, of 50, at Lanesborough. Soon after reaching Athlone, Ophthalmia became very prevalent among the troops, and we had generally forty cases in hospital at a time. All through the winter its spread was very gradual; and as an idea was entertained that its existence was attributable to the men themselves, it is possible that sufficiently energetic means were not employed to arrest its progress. At least, so I believed. The men were constantly kept at their duty, and no precautions taken for separating those slightly affected and convalescent from the others. In the following spring, about May 1849, the disease had regularly got hold of the regiment, and then I suggested the propriety of inspecting the troops daily, when all cases shewing the slightest symptoms of the disease were at once taken into hospital, and all the convalescents were placed in a detached barrack, apart from any communication, even indirectly, with the other men; and as these latter got well they were drafted to their respective companies. All the men in the regiment were ordered to wash in separate vessels, and to use their own towels only, each man having two; and the sergeants and subaltern officers were held responsible for these regulations being complied with. Even with these precautions, the disease made such progress, that it was with great difficulty we could check it, and that was not fully accomplished until we were about to leave the locality, in the spring of 1850.

"We had many formidable exciting causes to contend with, besides the extent of the existing disease. Athlone is well known as a locality where Ophthalmia constantly prevails. Nearly every regiment quartered there, for many years past, appears to have been affected with the disease. I believe the main cause of its prevalence there depends upon the great exposure of soldiers at night-time, mounting guard on those cold, bleak, unprotected positions upon the batteries and lines adjoining the bank of the River Shannon. The atmosphere is the dampest that I ever experienced, except, perhaps, in India, during the rains. The cold damp wind, coming down off the lake and the bogs at night, used to give the men Ophthalmia as if *struck* by the disease.[1] I have seen

[1] One of the men invalided from the 31st regiment told me to-day, that he went on guard perfectly well at twelve o'clock at night, and was unable to remain on his two hours, his eyes had become so much swollen and so gravelly.

four and sometimes six men come off guard into hospital, with severe conjunctivitis, who had mounted guard perfectly well. I know not if you are aware that soldiers' guard-rooms are about as small as they well can be; and that, when a sentry is relieved, he goes into the guard room, where he and his comrades lie down, in their great coats, altogether, huddled as close as possible. They shut the doors and windows, and light a large fire; and are, consequently, almost stewed. Then, when it comes again to their turn to go on sentry, they change *at once* from this great heat to a two hours' watch on the lines, exposed to the cold damp wind I have described. I am satisfied that it is this atmospheric influence, and this sudden transition, that produces Ophthalmia at Athlone, for many reasons. One will suffice. The Scotch Greys were quartered there with us, as also a battery of Artillery. These were both replaced by the 4th Light Dragoons and another battery of Artillery. Now, the men of these corps are similar to ours in every respect; they were quartered in the same barrack, and had the same rations, etc.; but they had not a single case of Ophthalmia among them; I believe because they never mounted guard as our men did. I do not believe that the disease was produced by the men themselves. Some of the best soldiers we had were attacked with it, and many of the bad ones escaped. From July 1848 to March 1850, 430 cases were admitted into hospital. Only one man went blind with both eyes. He had violent purulent Ophthalmia; and, in spite of the most active means, lost his sight in twenty-four hours. Four lost one eye each. Two of these were invalided, and two are still in the regiment; and twelve others were sent to Dublin, with chronic Ophthalmia, granular lids, opacities of cornea, etc., and were invalided in consequence. During the two years that we were quartered at Athlone, only two men upon the out-stations were attacked by the disease. They each lost an eye. I think you will allow that, out of 430 cases, for only one man to go quite blind, and four to lose one eye each, was fortunate. We were in the habit of making the men march three or four miles into the country every day, as soon as the acute symptoms had subsided, and we found no means more effectual in improving their health. We never confined them to bed, except in the inflammatory stage, and we gave them a generous diet, wine, and porter."

From this valuable communication we learn many useful facts, with respect to the exciting causes of the prevailing epidemic at Athlone, which will, I trust, be properly applied by those whom it may concern, civil and military. We likewise learn the fact, that in persons as healthy as soldiers, for whom every appliance and comfort is provided and the most judicious treatment employed, out of 432 cases, including those upon the out-stations, permanent mischief may result in seven, and twelve more be invalided; making nineteen in all, or one in every twenty-three, on the most moderate calculation.

It is no small satisfaction to me to find that the means which I recommended in Tipperary were immediately put in force, the guardians having, in a few days after my visit, procured suitable accommodation, and having had all the children labouring under Ophthalmia and its effects in the Meeting-house Lane Hospital removed to a country seat, some miles off. And in Athlone, the patients so miserably located in the Malthouse were forthwith removed to the parent Workhouse. In both localities the spread of the disease has, I understand, nearly ceased.

How far the disease has prevailed throughout the Irish Unions generally, I have no means of stating with any degree of accuracy; but I know that it has spread extensively throughout the south and west. At Limerick, in particular, I am informed by Dr. Kavanagh, it has spread extensively in the Poorhouse, and has also prevailed among the lower classes in the town, and in the neighbouring country. Upwards of 2000 cases occurred in the Workhouse and Auxiliary Workhouses of the Union since June last. It has likewise broken out in Kerry, at Tralee, and Dingle, and also at Kenmare. It has recently appeared in the Kilmallock Union, and in the Workhouse at Loughrea, as I have been informed by Dr. Lynch. Ballinasloe Union has also suffered from the epidemic. In Galway Poorhouse, Dr. Brown informs me, it broke out in June, so as to create alarm for its spread; and at the same time it appeared in the Auxiliary Workhouses of that Union, both of them situated in the country. It appeared chiefly among the boys and girls under fifteen years of age; and it was remarked that it never affected those who were labouring under dysentery. The disease was at its height in September, when 102 cases occurred. It has also prevailed slightly at Loughlinstone, near Bray.

What the exact number of persons may be, who have been totally or in part deprived of sight by this epidemic in our Irish Workhouses, I have no means of ascertaining; but I have addressed a letter to the Commissioners, enclosing a form for obtaining the desired information, which has been adopted. The returns which this circular will produce, together with the results of the Census about to be taken, will afford the true statement; and upon a subject of such importance, it is of great consequence that accurate statistical information should replace the loose assertions so frequently made, not only as regards this, but with respect to everything relating to this country.

It is quite manifest that, if the disease continues to spread, a great number of persons must, even with the greatest care and under the most judicious treatment, become blind. It cannot be expected that, in the impoverished state of this country, the friends and relations of such can receive them back into their homes; and it would scarcely be just to leave them in the hospitals and poorhouses. Some suitable asylum, where they will be properly taken care of, and educated according to their capacity, must, in process of time, be erected for their reception and maintenance. The last Poor-Law Act provides for such. At section XIV we read: "And be it enacted, that the Guardians of any Union may send any destitute poor deaf and dumb or blind child under the age of eighteen, to any Institution for the Maintenance of the Deaf and Dumb or Blind which may be approved of by the Commissioners, with the consent of the parents or guardians of such child, and may pay the expense of its maintenance there out of the Rates raised under the authority of the said first-recited Act." This, I believe, is the only country in Europe in which there is no general asylum for the destitute blind.

Dublin, December 1850.

ADDRESS TO A MEDICAL STUDENT. Second Edition. pp. 167. Oxford and London: 1850.

THE Profession of Medicine does not hold, in the estimation of the public, the rank to which it is undoubtedly entitled. While medicine as a science has made rapid and gigantic steps, its professors have by no means reaped rewards proportionate to their meritorious exertions, and to their sacrifices on behalf of the community. While the sister professions of divinity and of law are upheld and defended in their rights and privileges by the strong arm of the legislature, and by codes of etiquette and of ethics self-imposed by those who constitute the legal and clerical bodies, the profession of medicine, which is inferior to no other in the extent and variety of its studies, or in the nobleness of its aims, is left to struggle in the best way it can with apathy, and sometimes with contumely from without, and with angry dissension from within. This state of things has long been recognised, and has frequently been deplored: but although innumerable remedies have been recommended to counteract or to remove the growing evils of our condition, a cure still seems far distant: for while each one who has applied himself to the task has found it easy to point out the fallacy of plans advanced by others, no one has been able to propose an effective substitute. In the present condition of the profession, it appears to us that self-reform is needed as a prelude to legislative enactments. Before the legislature can act with efficiency, so as to satisfy the expectations of individuals and to protect and benefit the public, and before the corporate bodies can so liberalize their policy as to consult the hopes and wishes of the mass of the profession, it is absolutely necessary, in our opinion, THAT ITS MEMBERS SHOULD BE UNITED AMONG THEMSELVES; that they should lay aside their petty jealousies and party struggles for pre-eminence, and apply themselves with one heart to the great preliminary work of effecting a MORAL REFORMATION. While, therefore, we

fully admit the necessity of Reform in the Medical Corporations, and while we profess our wish and our determination to struggle for obtaining from the Legislature a recognition of the just claims of the many, we nevertheless most strongly recommend that the progress of reform should be from below upwards ; and we feel convinced that by harmony and union—by honourable and continuous exertion—by individual and collective attempts at internal regeneration—the progress of improvement, though tranquil, will be so irresistible, that neither the Legislature nor the Corporations will be able to refuse compliance with demands justly made, and respectfully urged. But while ignorance, quackery, and folly, still (and we speak it to our shame) disgrace our noble profession, how can we command the sympathies of the public, or induce the Legislature or the Corporations to listen to our complaints, or redress our wrongs ? We therefore conceive that the opening of a new year affords an appropriate opportunity for offering some remarks on Medical Ethics.

The sentiments which we shall profess, and the views which we shall advocate, are those which this Journal has, from the commencement of its existence, consistently maintained. We shall continue to enforce the adoption of a lofty tone of morality in our intercourse with our brethren and with the public at large ; we shall, as far as lies in our power, give honour to whom honour is due, irrespective of rank, fame, or position ; and we shall hail with joy any attempt to introduce wholesome reform, from whatever quarter it may come—

"Tros Tyriusque mihi nullo discrimine agetur".

The publications, of which we have prefixed the titles, are all devoted more or less to the consideration of the subject of Medical Ethics, or in other words, of the mutual duties and obligations which the members of the Medical Profession owe to their brethren, and to the community at large. The first work which stands on the list is a most useful and valuable essay upon this subject, written by a transatlantic physician, and edited in a very creditable and judicious manner by our countryman, Dr. E. Bentley. The Transactions of the American Medical Associations are highly interesting, as showing the praiseworthy efforts which are being made by our brethren in the New World, to harmonize the conflicting and discordant elements which constitute the Medical Profession in that quarter of the globe. From the perusal of these Transactions, it is somewhat consolatory to discover that, however much we may lament the condition of our profession in the British Empire, things are still worse in the United States. We find that complaints are made of the inefficiency of the education of medical students, of the general absence of sound preliminary instruction, and of the laxity of the examinations for degrees in medicine and surgery ; and we find complaints exactly similar to those made in our own country against the prevalence of quackery in its various forms, and denunciations of practices which, although adopted by persons within the ranks of the profession, are nevertheless inconsistent with the character of honourable men. To remedy these evils, associations have been formed in various parts of the United States ; and, in a spirit of hearty co-operation, we emphatically wish them success in their laudable endeavours.

But, instead of analysing the contents of the volumes now before us, it is our intention to offer some remarks founded upon a perusal of their pages, and which we believe to be imperatively called for by the circumstances of the present day. Although our remarks are intended for all, it is yet our object in the present article to address ourselves more particularly to the younger members of the profession. It is from the present generation of students that the practitioners of future years must arise, and it is impossible to overrate the importance of an early adoption of sound principles of thought and action.

We cannot omit to notice, in the first place, the heavy responsibility which is incurred by the medical practitioner, and the necessity which exists, that he should be a moral and religious man. But, besides these qualities, there are others hardly less requisite; he must cultivate all the gentler feelings of the human breast, must bear with patience the irritability which attends upon disease and suffering, must witness scenes at which humanity instinctively recoils, and must often inflict pain that good may ensue. Whatever branch of the profession he may intend to pursue, he must be prepared for labour and self-denial, and must waste the midnight oil in solitary study, as well as enter into the active duties of attending upon the sick. And his reward, we regret to add, will often be found only in the approval of his own conscience; for many of those to whom he must minister are the outcasts of the earth, who nevertheless claim at his hands the same attention which would be bestowed upon the most favoured of their fellow-creatures.

Having thus premised the indispensable necessity of morality and religion, together with the virtues which follow in their train, in forming the character and directing the conduct of the medical practitioner, we shall draw attention to a subject on which much has been said and written, but hitherto not so much as the occasion demands: namely, the importance of Preliminary Education. We cannot plead guilty to any exaggeration, when we declare that half the evils of the profession may be traced to a deficiency in this particular. By thrusting uneducated or ill-educated men into the ranks of the profession, the whole medical community is injured and degraded; and we may advance a step farther, and declare our conviction that the multiform shapes assumed by quackery are, in a very great measure, to be traced to the want of sound principles inculcated in youth. The gross absurdities of homœopathy and hydropathy could never have been carried into practice by men who were in the slightest degree acquainted with the principles of logic, or who had taken any trouble to endeavour to trace effects to their causes. The mere fact that persons have been cured under the treatment, is by no means conclusive evidence, for persons have recovered under erroneous treatment and in the absence of all treatment, so great is the power of the *vis medicatrix naturæ;* and even were such cures much better authenticated than they are, there would still be an utter absence of all proof of the truth of the dogmas on which these pseudo-philosophers build the foundation of their practices.

When we argue for the necessity of a sound preliminary education in the case of those who are to be educated for the medical profession, we do so on no narrow grounds; we do not assert that it is absolutely essential that prescriptions should be written in Latin, or that the future practitioner of medicine must necessarily draw his professional knowledge from the original writings of Hippocrates, Galen, or Celsus; but we maintain, that without some training of the mind in classics and mathematics, a young man is wholly unable to comprehend even the alphabet of medical science. On commencing his lectures, he is met at the threshold of his medical studies by a host of names derived from the Greek and Latin languages, which have been very generally, and we think very justly, employed in the construction of our scientific nomenclature; and the terseness, the perspicuity, and the expressiveness of those languages adapt them most admirably for the purpose. Again, in the study of chemistry, the principles of the exact sciences are indispensable; for chemistry is not a science of hypothesis and speculation, but of experiment and reasoning. And in the study of physiology, the questions proposed for consideration are still more difficult; for, in addition to the mechanical agencies which affect the condition of matter, the mysterious principle of vitality is introduced to modify or control the ordinary laws of nature.

When we contrast the condition of the medical practitioner with that of the clergyman, the comparison is greatly to the disadvantage of the former ; and if the reason of this disparity be asked, it will be found, we think, in the general superiority of the preliminary education enforced upon the ministers of the Church. Were we to make use of the same line of argument as that which has been adopted in relation to our own profession, we might urge that a knowledge of the classical languages was unnecessary to a clergyman of the present day, that the learning of our ancestors had accumulated for us such a mass of translations and commentaries that an acquaintance with the originals was superfluous, and that good common sense and a fair knowledge of the mother tongue were the only accomplishments necessary for the ministers of religion ; but law and custom have (and we think very properly) ordered that it should be otherwise, and the future clergyman is compelled, before he enters upon his theological courses at all, to pass through a definite prescribed course of classical, mathematical, and logical studies. No one ever argued, so far as we are aware, that in order to teach the doctrines of Christianity, it was absolutely essential to be initiated into the mysteries of heathen mythology, or to be thoroughly versed in the intricacies of Greek metres ; but that these and similar investigations tend to strengthen the mind and to enlarge its faculties, is undeniable ; and we accordingly find, that, in the majority of cases, those who have distinguished themselves most in their University career have been the most celebrated characters in after life. It is not argued that such studies as those we have alluded to, are essential to the clergyman, the barrister, or the physician, in the discharge of the professional duties which fall to the lot of each ; but it is maintained, that the exercise of the mental faculties which attends a scholastic career is eminently conducive to that discipline of the mind, which enables a man to practise with success in whatever department his taste or his fortunes may point out.

But it may be urged, that if a high standard of preliminary education were required from all professional men, there would not be found a sufficient number of persons who would be qualified for their respective duties. This argument we have, on a former occasion, shown to be wholly fallacious ; for, although a vast proportion of the clergy receive very small incomes, it is a well-known fact that there is no diminution of the number of those who repair to our Universities with a view to the Church, and who, with the scanty emolument which they have in prospect, nevertheless enter with zeal and assiduity upon the laborious and expensive curriculum enjoined by the authorities.

If, then, it be universally admitted, that a sound preliminary education is essential in the training of the clergy, and if the clergy themselves cheerfully adopt the collegiate course which is prescribed to them, it is surely equally necessary that the education of the medical practitioner should not be neglected. The latter is, or should be, on a level with the members of any other profession whatever ; and there is nothing in his condition, except want of education, that can make him forfeit this his proper rank.

We have just shown, that a knowledge of the classical tongues is indispensable to a comprehension of the literature and current language of the Medical Profession ; and that, without such a knowledge, lectures, discussions, and treatises on medical matters, are comparatively valueless, and almost unintelligible ; and we have also insisted that an acquaintance with the exact sciences is no less necessary, to direct the mind in a definite course,—to collect and analyse the multitude of facts presented to the memory,—to arrange and methodize the stores of acquired knowledge,—to retain what is valuable, and to reject what is useless or unimportant,—to lead to the formation of just conclusions, and the rejection of false, foolish, and visionary hypotheses, such as the dreamy mysticisms of homœopathy, hydropathy, etc. But these,

after all, are mere utilitarian arguments ; and we do not advocate the pursuit of knowledge, merely by counting up how much it will eventually be worth to the possessor. No ! we argue for the intellectual improvement of our profession on much higher grounds. We see everywhere around us that education is marching on with rapid and gigantic strides,—that a thirst for knowledge is springing up among all classes of society ; and we cannot allow that the practitioners of medicine, one of the noblest, most ancient, and most useful of the arts, should be distanced in the honourable competition. We cannot endure that, while mathematicians and philosophers are subjugating the material universe to the empire of the mind,—while valleys are literally exalted, and hills made low, by human art,—while even time and space are made subservient to the control of man—we cannot endure that medicine should be deserted by philosophy, and tainted with the discreditable alloy of empiricism. We should indeed rejoice if we could believe that all empirics were (as we believe many to be) well-meaning, though weak-minded men : but we fear that in too many cases the name and titles of the profession are usurped to cover the nakedness of rampant fraud, and to assist more effectually in deluding the multitude. Against such a lamentable condition of things, we believe one of the most effectual barriers to be an improvement in the Preliminary Education of the Profession, which would undoubtedly tend to check, if not altogether to subvert, such tendencies as those to which we have just alluded. The ridiculous and baseless conclusions at which quackery jumps, could never be entertained for one moment by minds trained to accurate mathematical induction and demonstration : and the idea of deluding the public for selfish objects could surely be seldom entertained by persons, who were made acquainted from youth with the glowing pages of the Greek and Roman sages, dramatists, poets, and philosophers, who wrote not for their own age, but for all time, and whose language and whose sentiments will endure as long as a perception of the good and the beautiful is left among the nations of the earth.

But we may be asked to state our views as to the nature of the preliminary education which ought to be recommended or enforced, in the case of those who purpose to enter the Medical Profession. Now this must, of course, vary with the nature of the case ; but, as a general rule, we know of no course of instruction which is more complete and efficient than that required for the Matriculation Examination at the University of London, which takes place once a year, and is open to all students who have passed their sixteenth year. This examination, which is somewhat similar to the Previous Examination at Cambridge, comprises a fair acquaintance with the Greek and Latin languages, and the mathematics, including algebra and geometry ; to which are added the subjects of chemistry or natural philosophy, the principles of English grammar and composition, and the elements of ancient and modern history. In our opinion, the whole of the youth of our profession ought to be subjected to this, or a similar examination; for there is no part of it which does not contribute to enlarge the views and strengthen the intellect. For it should not be forgotten, that the medical practitioner is, or ought to be, essentially a gentleman, and should possess, in addition to his medical knowledge, such an amount of general information as may qualify him to mix in any society. If, therefore, circumstances should prevent him from passing the London University examination, or from graduating at one of the other universities, we consider that he should possess, *before entering the Medical Profession*, at least such an amount of classical and mathematical knowledge as may be acquired at a good school ; and without the possession of this amount of knowledge, he should not be recommended, or indeed allowed, to enter the profession at all ; for, independently of all higher considerations, we conceive that a person destitute of this amount of information is quite unable to follow with any profit a train of medical, chemical, or physiological reasoning, or, indeed, even to comprehend the technical terms used in science. He may, indeed,

learn to apply bandages and extract teeth; he may acquire a certain degree of dexterity in putting on splints; and he may even be capable of prescribing a blue pill and a black draught, without much compromising the safety of the community: but such are not the only necessary accomplishments of the medical practitioner, who is often called upon, not only to draw largely upon his stores of actual knowledge, but to employ the processes of subtle and refined reasoning.

We are most happy to notice, in terms of the highest commendation, the encouragement given, at one or two of our hospitals, to the prosecution of general literature and science among the alumni of our profession. We find that, at St. Thomas's and the Westminster Hospitals, scholarships are instituted for students *who are about to commence their medical career*, and who can pass a successful examination in the Greek, Latin, and French languages, and in the elements of Mathematics. We should most earnestly desire that all the hospitals, and medical schools, would follow so excellent an example; and we should rejoice if the examination were, in all cases, made compulsory, instead of optional.

It may be argued, that it is difficult, if not impossible, for the mass of medical students to reach the standard of education which we have just been recommending. We answer emphatically, that there is no difficulty at all in the matter. It may also be urged, that the system of apprenticeship is inimical to the acquisition of general preliminary knowledge. Now we maintain that a boy of average intellect and application, if placed at a good school, may, by the time he has attained the age of sixteen, acquire a sufficient amount of knowledge to meet the exigency of the case, and be enabled to pass his examinations at the age of twenty-one, even under the disadvantage (if it be one) of an apprenticeship. But we strongly recommend that a boy should after leaving school be sent for a year, at least, to some college, before entering upon his medical career. This, it is true, would delay his passing his examinations until the age of twenty-two, supposing the apprenticeship clause to be still in force. But we are quite at a loss to discover how any injury would ensue, either to the individual, or to the public, by this delay of a year; on the contrary, we think it would be highly beneficial; and we cannot too strongly condemn the practice of granting diplomas at the early age which is now usual. But, allowing matters to stand as they do at present, we have shewn that there is no difficulty whatever in a pupil acquiring a sufficient amount of general and medical knowledge, in the time at present allowed for the purpose.

With regard to the system of apprenticeship, we have already, on a former occasion, expressed our opinions. We neither argue for its continuance, nor press for its abolition: but, so long as the system is permitted to continue, we deem it more advisable to endeavour to increase its utility, than to denounce its abuses.

In leaving this subject, for the present, we repeat our conviction, that THE WANT OF PRELIMINARY EDUCATION among the members of the Medical Profession, is THE GIANT EVIL of our community in the present day. Without a sound basis of general information on the part of students, the efforts of lecturers, professors, and examiners, however well directed, are of little avail. We do not expect perfection under any circumstances; nor do we suppose that, under any system whatever, the members of the Medical Profession will be exempt from the faults, the follies, and the vices of other men: but we strongly maintain that the best—nay, the only safeguard against the inroads of quackery, the prevalence of visionary theories, and dishonest methods of practice, is to be found, in the inculcation of sound religious and scientific principles in early life.

(To be continued.)

Die Geburten missgestalter, kranker, und todter Kinder. Von Dr. Anton Friedrich Hohl, ordentichem öffentlichen Professor der Medicin und Geburtshülfe an der Universität zu Halle, etc. pp. 382. Halle: 1850.

[The Births of Misshapen, Diseased, and Dead Children. By Dr. A. F. Hohl.]

Dr. Hohl has, with considerable research, collected and arranged a large amount of information concerning the various malformations, diseases, and other accidents, to which the fœtus is liable: and has endeavoured to illustrate the practical bearing of this subject, in relation to the process of parturition. He treats successively of Malformation, Intra-uterine Diseases, and Dead Children.

Malformed Children. After a carefully compiled historical introduction, the author gives the following classification of the Malformations of the Fœtus.

Class i. Monstrosity from impediment to the vegetative and formative processes:

A. Of individual parts: (*a*) Head; (*b*) Extremities.

B. Of the entire body: (*a*) Acormous; (*b*) Amorphous.

Class ii. Abnormal connexion and union.

A. Abnormal Connexion:
- *a*. Of the Fœtus with parts of the ovum.
- *b*. Of the Fœtus with accessory and supernumerary bodies (parasites).
- *c*. Of two perfectly formed independent individuals, neither preponderating over the other, by means of a band.

B. Abnormal Union:
- *a*. Of individual parts.
- *b*. Of the corresponding parts of two individuals: (*a*) Malformation, with spurious fusion of parts; (*b*) Malformation, with true fusion.

Class iii. Malformations produced by mechanical causes:

a. From narrowness of the containing cavity.

b. From twisting of the umbilical cord round some part.

c. From abnormal membranes and bands.

These subjects are treated at length under the separate heads of Diagnosis, Influence on the Process of Parturition, and Treatment. The plan upon which the work is written prevents us from attempting to give a detailed analysis: we must therefore be content with translating a few extracts as specimens.

"Acephalous Monsters. In describing this form of monstrosity, we proceed from the more to the less perfect, according as the defect extends from above downwards, and amounts even to absence of the neck and thorax. The more the imperfection of development extends downwards, the greater is the defect in the upper extremities. Acephalous monsters generally have a short round body, with œdematous swelling of the cellular tissue.

"Characters. 1. There is a tumour in the place of the head, in which bones may be felt. The projection is either a round spongy body, or a cavity formed of spongy bones, and covered with a periosteal membrane, or a round protuberance covered with skin, and furnished with holes and excrescences, representing the eyes and nose. This protuberance is a rudimentary cranium, in which the bones of the face are absent, but which possesses frontal and occipital bones. 2. There are no bones; and the rudimentary head feels like a bladder, a cartilaginous tumour, a mulberry-like swelling, a small warty projection, or a membranous lump covered with hairs. The cervical vertebræ are present. 3. The cervical vertebræ are either imperfect or wanting; in the first case, they are fused together, so that they may be mistaken for cranial bones. The head is entirely absent. 4. The dorsal part of the spine consists only

of single vertebræ: the upper limbs are wanting. (Atkinson, *Phys. and Med. Journ.*, 1804, No. 65.) 5. The lumbar vertebræ are either in proper number, or deficient, and the upper end of the body is round, or forms a blunt cone, and sometimes has a small fleshy or membranous excrescence, which may be furnished with thin, or even with thick hair, and is not unfrequently the point of insertion of the umbilical cord. 6. The malformed fœtus is formed only of the bones and muscles of the pelvis and lower extremities. The umbilical cord, in this form of monstrosity, is generally short and thin.

"Symptoms during Pregnancy and Labour. The acephalous fœtus generally occurs in twin and other multiple births, and is rarely found alone. It occurs both in primiparæ, and in those who have borne several children. The mothers are almost always very prolific. (Busch and Moser, *Handbuch der Geburtskunde, Art. Missbildung*, s. 521.) According to J. F. Meckel, pregnancy reaches its full term, and the accompanying twin is usually mature. (*Pathol. Anat.*, ph. I.) Of twenty-two cases, collected by me, the time is given in eleven; in three, parturition took place at the full period; in one, at the sixth month; in four, at the seventh; in one, at the eighth; in one, at the ninth; and one is merely said not to have arrived at the full term. Of forty-seven cases, mentioned by Tiedemann, fourteen were born at the full period, and thirty-three were premature. The presentation is generally footling; at least such was the case in eight instances, in which the presentation was recorded. The perfect child is born first, and the other follows in from half-an-hour to twelve hours. The obstetrician has here especially to observe: 1. Whether the rudiments of the head are distinct, or entirely wanting. 2. Whether the upper limbs are deficient, or entirely absent. 3. The conical or round end of the trunk, with or without ribs, more or less distant from the umbilicus. 4. The failure of movements after the birth of the first child. 5. The presentation of the feet, which are usually malformed. 6. The usual imperfect development of the generative organs." (pp. 61-3.)

The chapter on the treatment required in the various kinds of malformation is interesting. We quote the general principles which are laid down by the author.

"In every case, where there is a mechanical impediment to labour, the possibility of the presence of monstrosities must not be forgotten, especially when no impeding cause can be discovered to exist on the part of the mother. 2. If the presence of a monstrosity be recognised as the cause of impeded labour, a repeated exploration is indispensable for the choice of a suitable plan of treatment: the kind of malformation, and the relation of the parts to each other and to the maternal passages, must be ascertained as accurately as possible. The fulfilment of this indication is often the more difficult, as we have to determine not only normal, but often abnormal relations. The pelvis may be of usual size, and yet may not suffice; and a slight, even unconspicuous narrowing may be important, according as the malformation belongs to either one or the other class. On this knowledge depends the choice of the operation, and the manner of performing it. 3. With regard to the mother, the mildest and least painful treatment is to be adopted: the hand is to be preferred to instruments; and due regard must be had to the safety of the child. 4. If the child be alive, its chance of living, according to the kind of monstrosity, must also be borne in mind. The duration of viability must be considered; the child may live only a very short time, or even for a considerable period." The author here gives a table from Devergie, shewing the viability or non-viability of various forms of monsters.

"5. If the obstetrician have formed his opinion as to the viability or non-viability of the misshapen fœtus, he must also remember, that a decided solution of this question is, in many cases, impossible before birth, as the condition of the child may be undiscovered: he must also bear in mind, that there are exceptions to the rule, and that a non-viable child may yet live during parturition. We are especially required to consider this, in con-

junction with the latter part of the third rule, (*a*) when we are called on to deliver a malformed fœtus, and (*b*) especially when we can choose between several modes of operation for the delivery of the mother, or (*c*) when the death of the child is demanded for the safety of the mother. (6.) If we are called on to deliver a child which is known to be malformed, it is well to consider how it may be born alive. Its viability should be assumed ; and our third rule should be attended to, in the choice of the mildest and least injurious mode of operating, the hand being preferred to instruments. We thus conscientiously fulfil our duty both to the mother and to the child, and do not bring the former into danger through extreme and violent measures. 7. If we have the choice of several operations, we must not think the life of the child of little value, because it is malformed ; nor must we be careless of giving pain to the child, while we spare the mother ; but we must choose that operation which we believe will terminate the labour securely, quickly, and happily for *both* individuals. That operation is not always most free from danger to the mother, which is but little felt by her, as perforation, embryotomy, etc. ; but very often that which is more painful, is at the same time more sure and speedy. 8. If the death of the child appear to be the last resource for the delivery of the mother, we have to consider whether or not the Cæsarean operation should be performed, because the child is malformed. This question is passed over in silence by some obstetricians, while by others it is answered in the affirmative, and by others again in the negative". (pp. 163-170.)

This quotation will sufficiently show the principles by which the author is actuated. His object throughout is to save both mother and child, when there is the least possibility of accomplishing this. When the death of the child is unavoidable, the importance of attending to its safety cannot be put in competition with that of the mother. "But", says Dr. Hohl, "the obstetrician must not lay his hand too hastily on deadly instruments, because he has recognised a monstrosity ; but he must endeavour to preserve both mother and child, if this can be done without prejudice to the mother". (p. 173.) The treatment of the various forms of monstrosity is next passed in review ; and a considerable portion of this part of the book is devoted to an extended and lucid examination of the means which have been recommended for the delivery of double monsters. The author gives the preference to turning : but he also advocates, when required, perforation, or the use of the forceps.

The following extract from Dr. Hohl's remarks on embryotomy, of which he admits the necessity in circumstances of extreme difficulty, will be interesting in connexion with the memoir of Dr. Chailly-Honoré, on Amputation of the Arm in Shoulder Presentations, of which we propose to give a translation in our Digest of the Journals.

"It is a question whether the removal of a limb can be necessary ? I am a great enemy to the use of cutting instruments in midwifery, and prefer the hand, so far as it is at all possible to use it alone without danger to the mother. . . . . But it is undeniable, that the presentation of an arm may present an insuperable obstacle to manual assistance, and its removal may spare the mother much pain, and the operator much toilsome and fruitless exertion. In such cases, the operation is a necessary evil." (p. 218.)

Diseased Children. This subject is treated of under the following heads.

1. Diseases of the Fœtus connected with debility of single parts or of the whole body.
2. Diseases of the Fœtus connected with increase of the bulk of single parts of the body. Under this head are included, (*a*) Hydrocephalus, (*b*) Thoracic and Abdominal Dropsy ; (*c*) Watery Sacs and Tumours ; (*d*) Enlargement of Internal Organs.
3. Diseases of the Fœtus, with increased size of the whole body ; including (*a*) Cutaneous and General Dropsy ; (*b*) Hypertrophy.

In his preliminary remarks to this chapter, the author points out the importance of more attention being paid to the diseases attendant on intra-uterine life. He enters on a general consideration of the causes, which he refers in part to the parents, especially the mother, and in part to the fœtus and its appendages ; and also makes some remarks on the symptoms produced, both with regard to the mother and the fœtus.

From this interesting and instructive chapter, we can make but one extract :

"Enlargement of Internal Organs. We find enlargement of the liver, of the kidneys, and of the urinary bladder, described by authors. The enlargement sometimes exists alone, and sometimes accompanies other diseases, especially dropsies.

"The *impediment to labour* is increased when other conditions are present which augment the general size of the body. Thus, in a case recorded by Seulen (*Neue Zeitschrift für Geburtskunde*, Band ii, p. 17), there was enlarged liver and general dropsy. In cases related by Müller, Schlesinger, and Vernhes, the liver, kidneys, and bladder, were respectively enlarged, in conjunction with ascites. The simple enlargement of an organ will also impede labour. Mansa relates a case in which the head was torn off with one arm ; the impediment consisting in a greatly enlarged kidney, so that extraction could only be effected after removal of the abdominal viscera. (*Siebold's Journal*, Band xv, p. 3, 1836). Haase relates a case in which there was malpresentation, with prolapsed funis and enlarged liver ; delivery was only effected by turning and evisceration. (*Neue Zeitschrift für Geburtsk.*, Band xi, p. 362). Cases of enlarged kidney have been recorded by J. F. Osiander, Hoering, and Oesterlen.[1] In Osiander's case, the breech presented, and the pains had lasted a long time without any effect. A foot was brought down, when the body was discovered to be enlarged, apparently from dropsy. As the other foot could not be brought down, on account of the size of the body and its untoward projection forwards, extraction was completed with one foot. The child made a few convulsive movements ; it was at the seventh month ; there was no fluid in the peritoneal cavity, but both kidneys were nearly as large as in a grown person, and formed a prominence on each side of the abdomen. (*Gemeine Deutsche Zeitschr. f. Geburtskunde*, Bd., i, p. 167). In Hoering's case, labour came on three or four weeks before the full time. When the head was born, the pains ceased ; and the surgeon, after vain attempts to extract the breech, removed the head and thorax. Dr. Hoering found a tolerably large mass, after the removal of which, the rest of the child followed. The enlargement of the abdomen had been produced by the degenerated kidneys, which consisted of two large lobed masses. (*Würtemb. Medic. Correspondenzblatt*, Bd. vii, 1837, No. 16). In Oesterlen's case, the kidneys formed an enormous roundish tumour, filling the abdomen on each side. The child was born as far as the abdomen, which for some time resisted sharp labour pains and the traction exerted by the midwife. The child was dead. (*Neue Zeitschrift für Geburtsk.*, Bd. viii, p. 384). Other cases are related by J. F. Meckel, Chaussier, and Heusinger. The result was generally favourable to the mothers, although the children all perished.

"The *diagnosis* of such cases is important, but difficult, especially when dropsy is also present. When there is an impediment after the birth of the head, we have to remember that it may arise from adherent twins, from watery sacs and swellings at the lower part of the body, from abdominal dropsy, from distortion of the lower part of the spine, from the entrance of

[1] Intra uterine cystous disease of the kidney was made the subject of a paper by Dr. Cormack, in the *Edinburgh Monthly Journal of Medical Science* for August 1844. Dr. Cormack's paper contains, besides an original case, (illustrated by drawings,) the records, more or less perfect, of twenty instances, several of which are not referred to by Dr. Hohl.

the head of another child into the pelvis with the breech of the first, or from enlargement of the liver or kidneys. A careful external and internal examination will always explain the case, if we remember these facts, and do not allow the consideration of negative possibilities to remove our attention from what is actually present. If the enlargement is produced by a single organ, we find the abdomen more tense and firm than in dropsy; the abdominal walls resist pressure, and we meet with a solid body. This will point out the situation of the enlarged organ; and, if it be the kidneys, the abdomen is distended laterally. Even when there is fluid in the peritoneal cavity, a careful exploration will enable us to feel the enlarged organs. The diagnosis will be difficult if, as in Billard's case, labour is impeded from enlargement of the urinary bladder. The swelling is here more circumscribed than in ascites." (pp. 305-8.)

In the treatment of such cases, Dr. Hohl believes that much may often be done by careful manipulation of the body, without having recourse to instruments. But he allows that, in some cases, instrumental interference is absolutely necessary.

Dead Children. This is a well written and instructive chapter, but our space prevents us from making extracts.

The quotations which we have given from Dr. Hohl's work will sufficiently shew the amount of labour which he has bestowed on the subject; and the interesting and instructive method in which he has arranged his information. Without any pretensions to profound pathological reasoning, the treatise is highly practical; and every one engaged in obstetric practice, to whom it is accessible, must feel interested by the numerous cases with which it is interspersed, and receive valuable information on the treatment of a class of accidents attendant on parturition, which, though their occurrence be more or less rare, ought to be understood by the accoucheur.

Epidemics Examined and Explained, or Living Germs proved by Analogy to be a Source of Disease. By John Grove, M.R.C.S.L. Lond: 1850. 8vo., pp. 192.

The object of this handsome little volume, written in an agreeable style, and displaying no inconsiderable amount of multifarious reading, is sufficiently indicated by its title. The work consists of four chapters; the first being devoted to establish the Probability of Epidemic, Endemic, and Infectious Diseases depending upon Vital Germs for their Manifestations; the second to the Number and Value of Facts to support the proposition; the third to the Reasonableness of the Application of the Facts to the Inference; and the fourth to Results in Proof of the Tenableness of the Proposition.

Mr. Grove, almost at the outset, reasonably enough expresses a doubt whether we are much further advanced in the knowledge of the cause of pestilences, than the Jews in the time of Moses; and he subsequently adds, that all previous writers have signally failed to furnish us with any practical information. Impressed with a very natural conviction of the difficulty of the subject, the author, therefore, has applied himself, as he tells us, solely to the groundwork as the primary proceeding for a solid superstructure. But even with this limited direction of his labour, grave doubts are likely to be suggested by a careful examination of the arguments which he brings forward, whether he has, to any extent, succeeded in *proving* the dogma, somewhat prematurely laid down in the title which he has selected for his work. To our apprehension he has scarcely, in any appreciable degree, succeeded in lifting the veil of obscurity, or, we should rather say, of Cimmerian darkness, which rests on the origin of epidemic diseases, the subject remaining pretty much as he found it: all is dim, shadowy, and uncertain, as before.

In expressing this opinion, however, we utterly disclaim any intention of disparaging either the ability or acquirements of the author; on the contrary, we think he has succeeded as well as most writers, who may be tempted to essay the same task with no better materials. The truth is, that facts are entirely wanting, to afford any stable support for the hypothesis which he has espoused, and necessarily *ex nihilo nihil fit*. Indeed, in the existing state of our information, we look on a successful attempt to prove the doctrine referred to, not only as difficult, but simply impossible; nor is it within the compass even of the highest talent, to give permanency to any medical hypothesis, the groundwork of which has no better foundation than plausible conjectures, and analogical inferences. It is no doubt true, that a theory, if soundly based on an accurate observation of facts, may receive even strong corroboration from analogy; but to rely principally on the latter mode of reasoning, is to reverse the natural order of things, and appears to resemble somewhat too closely the architectural device of that ingenious people, described by the witty Dean of St. Patrick, whose custom it was to commence their buildings at the roof, and to finish them at the foundation. But to examine the subject a little more closely, suppose it were conceded (and this is perhaps going quite as far as the premises warrant,) that a certain degree of probability attaches to the causation of epidemic and infectious diseases by vegetable germs, cells, or sporidia, surely something more than analogical arguments, however plausible, will be required to win general assent to a doctrine so obscure and difficult. When we ask for facts, it will not surely be alleged that the so-called fungoid cells, seen by Mr. Spooner in variolo-vaccine lymph, or the microscopic discoveries of Brittan, Swayne, and Budd in the rejectamenta of choleraic patients, afford any solid foundation to this vegetable theory. Yet utterly insufficient for the purpose, as recent demonstrations have shown the alleged facts to be, the doctrine, we believe, has little else to repose on; and, as far as relates to cholera, it was unanswerably refuted almost as soon as it saw the light. To future advocates of the same hypothesis, it may therefore be reasonably suggested, as an indispensable preliminary to success, to demonstrate, in the first place, that vegetable germs, or spores of a definite character, are invariably present in epidemic diseases; and in the second place, that they are not present in other forms of disease, or in the ordinary conditions of health. This point once firmly established, it will be soon enough to speculate regarding their exact relationship to various maladies, to inquire how far they may be an effect and not the cause of disease, what it is that determines their periods of activity and of long abeyance, their capricious and uncertain movements, and in what manner they operate on the solids and fluids of the animal frame. But, supposing all this to be satisfactorily determined, even then so much would still remain to be elucidated, before we could derive from our investigation of the subject any practically useful knowledge, that we scarcely hope to see this mode of accounting for the causation of disease, transferred from the rank of a mere hypothesis, to the position of an established doctrine in science. At the same time, however, we believe, with the author, that the chemical and animalcular theories of disease are, in the present state of our knowledge, equally untenable; but it by no means follows, that if the views of Liebig, Kopp, and Simon, and of Henle, Holland, and Mitchell be erroneous, that his adopted theory is true. On the whole, we are constrained in candour to say that Mr. Grove has entirely failed to satisfy us that the origin of epidemics is to be found in living vegetable germs; nor shall we probably be the only exemplification of the statement with which he sets out, that "it is one thing for a man to convince himself, but a very different thing to be able to convince others".

But although Mr. Grove has failed to satisfy us as to the origin of epidemic diseases, we have much pleasure in stating that we have found a large fund of very agreeable and interesting information in his treatise. We had

marked several passages for transference to our pages, but we must content ourselves with one specimen, which the author quotes from Dr. Lindley's *Vegetable Botany*. Should the reader agree with us in thinking it very curious, we can with the more confidence refer him to Mr. Grove's volume for the further gratification of his taste.

"One of the most poisonous of our fungi is the *Amanita Muscaria*, so called from its power of killing flies, when steeped in milk. Even this is eaten in Kamschatka, with no other than intoxicating effects, according to the following account by Langsdorf, as translated by Greville. This variety of *Amanita Muscaria* is used by the inhabitants of the north-eastern parts of Asia, in the same manner as wine, brandy, arrack, opium, etc. is by other nations: 'The most singular effect of the *Amanita* is the influence it possesses over the urine. It is said, that from time immemorial, the inhabitants have known that the fungus imparts an intoxicating quality to that secretion, which continues for a considerable time after taking it. For instance, a man moderately intoxicated to-day, will by the next morning have slept himself sober, but (as is the custom) by taking a teacup of his urine, he will be more powerfully intoxicated than he was the preceding day. It is, therefore, not uncommon for confirmed drunkards to preserve their urine, as a precious liquor against a scarcity of the fungus. The intoxicating property of the urine is capable of being propagated; for every one who partakes of it has his urine similarly affected. Thus, with a very few *Amanitæ*, a party of drunkards may keep up their debauch for a week.'" (P. 167.)

Cholera in the Asylum. A Contribution to the Statistics of Insanity and Cholera. By Thomas Giordani Wright, M.D., etc., etc. 8vo. London: 1850.

The volume before us is, in part, made up of "Reports on the origin and progress of pestilential Cholera, in the West Yorkshire Lunatic Asylum, during the autumn of 1849, and on the previous state of the Institution"; but it also contains a detail, at considerable length, of the views of the author, who is Visiting Physician to the Asylum, on the diseases alluded to, as well as some practical and valuable observations on their most appropriate treatment. Various points, connected with both the mental and the bodily malady, are well elucidated by a number of elaborate statistical tables, as the reader will find on reference to the work itself, which is written with much candour, perspicuity, and cleverness. To enable the reader, however, to judge for himself, a few extracts are subjoined; and we only regret that our space will not allow us to draw at greater length on the valuable contents of Dr. Wright's volume.

"All experience in treatment of the insane proves, that a full and nutritious diet tends much to the recovery of the patients, in a majority of cases, even under maniacal excitement, as well as other forms of mental disease; an axiom which is corroborated by the fact, that in asylums, where the diet is liberal, the proportion of recoveries is generally larger than in those where it is more meagre."

The following "Proportion of recoveries to the numbers admitted into English asylums, in which pauper patients only are received, to December 1848": is extracted from the table at p. 40.

	Years Established.	Cured per cent. on admissions.
County Asylum of Lancaster	32	40·1
——— West Riding	30	41·9
——— Suffolk	20	42·1
——— Middlesex (Hanwell)	18	24·4
——— ——— Kent	15	27·7

The disparity here shewn, admits, we have no doubt, of a satisfactory explanation; but the fact is worthy of remark; and, still more so, "the comparative

expense of an equal number of cases, admitted early after being attacked with insanity, and of cases neglected and delayed. Of the former, all were cured, at a cost of about £9 each; while of the latter, those who died cost upward of £30 each, and those who remained about £15 each *per annum*": a tolerably forcible comment on the homely adage of "a stitch in time".

With reference to pestilential Cholera, it may be premised that Dr. Wright, in compiling his tables, restricts the term to those cases in which collapse was present. "Diarrhœa without collapse, therefore, does not constitute Cholera; livid collapse, with or without diarrhœa, does." But, on inspecting the tables, it appears that diarrhœa and Cholera prevailed epidemically in the asylum at the same period; the number of cases of the former having been two hundred, thirty of which ended in Cholera, and of the latter one hundred and thirty-two, in a given period; facts from which the reader may draw his own conclusion as to the relationship between the two maladies. The disease was very fatal, one hundred and six of the Cholera patients having died; the entire number being, as just stated, one hundred and thirty-two; and the number of inmates in the asylum amounting to six hundred and twenty. "By far the highest ratio of recoveries was among cases preceded by diarrhœa." And, in the majority of patients on full diet, their illness ended in diarrhœa only; while a larger proportion of those on common diet were liable to Cholera, and were chiefly attacked without premonitory symptoms" (p. 72). Dr. Wright attributes the outbreak of Cholera, in the asylum, to infection; but the facts, as detailed by him, will not be universally assented to as demonstrative of his opinion. The following remarks on the symptoms are interesting: "Two peculiar features of the cramp accompanying Cholera are, that it was not confined to the stage of collapse, and that the spasmodic rigidity was almost exclusively in the flexor muscles" (p. 99). Again, "The urine was not suppressed so invariably as it is often said to be in Cholera; for we find that one-third of the patients passed urine during the period of collapse; that is in twenty cases, of whom three recovered, and seventeen died. Some made water copiously while livid, and almost pulseless" (p. 101). "Of consecutive fever we had very few examples. The general disturbance of Cholera abated gradually, and the patients became convalescent, without any intermediate stage".

Dr. Wright ascribes the seat of Cholera to the ganglionic system of nerves; but we have not space to examine his train of reasoning on the subject. We must, however, conclude with simply stating, that all modes of treatment, including chloroform, and the mercurial treatment of Dr. Ayre, were found alike inefficient in the blue stage of the disease.

APPENDIX. *We think it right to introduce in this place the following letter from* DR. KNOX, *of Strangford.*

TO THE EDITOR OF THE LONDON JOURNAL OF MEDICINE.

SIR,—In a copy of a valuable and ably written volume termed *Cholera in the Asylum*, by Dr. T. G. WRIGHT of Wakefield, which the author has politely forwarded to me, I find my attention drawn by him to the following passage: "In DR. KNOX's little volume, which contains an admirable epitome of the bibliography of Cholera, an erroneous inference is quoted from this note, which I feel sure the author will do me the justice to correct, when he has an opportunity. The deduction is, that fifty millions of persons having died, there have probably been, *at least*, twice as many cases of Cholera: not as Dr. Knox assumes, that out of a given number of cases one-half had died. The reader will, at once, perceive an obvious distinction between the inferences computed".

The explanation required by Dr. Wright, would most appropriately appear in a second edition of my Treatise; but as I am not exactly aware what time may elapse before that may be called for, I shall esteem it a favour if you will afford me, in the mean time, a brief space in your excellent and widely

circulated Journal, to adjust the question. The most satisfactory way of doing this, as it appears to me, is to quote *verbatim* both Dr. Wright's observation and my own, as follow:

"Therefore, averaging one-half of those attacked to have died, there must have been since 1817, upwards of *one hundred millions of cases* of spasmodic Cholera". (Dr. Wright in the *Lancet*, 1833, and reprinted in his *Reports*, p. 127.)

"Dr. Wright having calculated that of one hundred million cases occurring since 1817, one half have perished". (Knox's *Inquiry into the actual state of our knowledge of Cholera*, etc., p. 75.)

I at once admit that the distinction, pointed out by Dr. Wright in the passage which I have just quoted from his interesting Treatise, is sufficiently obvious; and this admission will, I trust, prove satisfactory to him. But as regards the actual state of the matter, it appears to me to be a distinction without any very substantial difference; for my inference as to the mortality of the disease was by no means solely founded on Dr. Wright's authority, but on a variety of tables which I had collected, and several of which are published in the body of *The Inquiry*. I may add, that in one of the most recent works on the subject (*Cholera and its Causes*, by Dr. Bushnan) the learned writer expressly states that "the mortality of the disease was never reduced much below what may be termed the natural standard: viz., about 50 per cent. of the cases treated, in any given and extensive series of attacks". At the same time, to avoid any misinterpretation of my views on the subject, it is necessary to state that my estimate alluded to, refers only to the more malignant types of the epidemic; for, believing as I do, that the different forms of Cholera are identical, it would, I conceive, be totally at variance with the fact, to assert that one-half of all the persons affected with that disease perish. On the contrary, I have expressly stated elsewhere that "in the milder kinds of Cholera, it is certain that few die, and even in its more aggravated forms many recover; so that the asserted inutility of medicine can only be applied to those cases, very numerous, no doubt, in which the epidemic exhibited an extreme degree of malignancy". *Inquiry*, p. 185.

Believe me to remain, Sir, very faithfully yours,

Strangford, Downshire. ALEXANDER KNOX, M.D.

PRACTICAL OBSERVATIONS ON THE DISORDERS AND DISEASES OF EUROPEAN INVALIDS ON THEIR RETURN FROM TROPICAL CLIMATES. By JAMES RANALD MARTIN, F.R.S., Surgeon Bengal Army, retired, late Presidency Surgeon, and Surgeon to the Native Hospital, Calcutta. Pp. 80. London: 1850.

When we consider the vast number of our countrymen who are compelled, by the exigencies of service or mercantile pursuits, to pass a large portion of their lives within the tropics, we must feel the importance of any discovery which can minister to their comfort, preserve their health, or prolong their lives. The natives of Hindustan and the negro inhabitants of our West Indian Colonies are fitted alike by nature and by habit to bear with impunity influences which are fatal to Europeans; and although the ratio of mortality among the latter has of late been diminished by the improved condition of society, of temperate habits, and more enlightened views on the part of those in authority, yet the number of victims is still great, and the list of those who return to their native land broken in constitution and health, is still formidable.

The work before us is the production of a gentleman, whose name has long been honourably known as co-editor with the late Dr. James Johnson of the standard work on Tropical Climates; and this modest volume is well calculated to sustain his reputation. It is a reprint from a cotemporary, and forms part of a series of Essays, to be published as a whole, we hope, at no distant time.

The diseases of Tropical Climates are as essentially abdominal as those of

this country are pulmonary; the whole force and tendency of external agents is to act in that direction. During the hot and rainy seasons in India, the perspiration is prodigiously increased, amounting in the latter season to an exhausting discharge; as if the very serum of the blood were exuded: and mark the consequence:

"The perspiration is not carried off by evaporation, while the transudation is enormously increased; thus heat accumulates in the body, and the local action of cold produces serious consequences, rendering the system susceptible of the least impression from cold or malarious influences, with a strong tendency to congestion in all the abdominal organs. The excessive watery discharge from the skin during this season must of necessity have the effect of rendering the venous blood unnaturally dense, and of thus causing the European to be more liable to congestive forms of disease. Dr. C. J. B. Williams refers the disposition to liver complaints, dysentery, and cholera to the stimulating properties of the blood, deprived, as we have seen, of more than its usual amount of water and of less of its hydro-carbon". (p. 6.)

This picture truly represents one phase of the existence of the Anglo-Indian, and let us see how he fares in the cold season:

"The now altered balance of the circulation and nervous function, the entire drying up of the surface, and the corresponding congestion of all the viscera; the less arterialized and viscid state of the blood; the diminution of the biliary, and the enormous increase of the renal secretions; the oppressed state of the cerebral, thoracic and abdominal functions, leading to the most formidable and complicated diseases, and to the suppression of chronic eruptions in a previous state of development, all render the cold season of Bengal the reverse of healthy". (p. 8.)

Fever, generally continued and of an active character, is the most common result of the hot season. In the succeeding rainy months, fever assumes a remittent character, with diminished vital action, and dangerous abdominal congestion. As the season advances, dysenteries, as well as fevers, become more frequent, severe, and complicated, the former implicating the whole of the abdominal organs. Cholera is most rife and fatal in April and May. The cold season is characterized again by its peculiar diseases; intermittent fever, with the sequelæ of tumid liver and spleen—insidious hepatic inflammation, terminating rapidly in abscess—apoplexies—paralyses—suppression of eruptions—and visceral congestion of every sort, now hold their sway, blighting the hopes and laying low the head of many an ardent and gallant spirit.

Great, indeed, is the change encountered by the Anglo-Indian on his return to Europe. "Here he enters at once, and without preparation, on a season of eight months of cold and moisture, in exchange for the same period of tropical heat and excessive moisture conjoined. This is a great revolution in climate; and it at once induces a corresponding physiological change in the system, stamping the individual with a peculiar physical character. The exhalant organs of the skin, which for so long a succession of years had been called into most violent action, now become sealed as if with a coating of varnish. From the previous extensive, equable, and sometimes violent determination to the surface of the body, he is suddenly subjected to an opposite action, an extreme dryness of the surface, amounting occasionally to a furfuraceous desquamation of the cuticle, and at other times to a miliary eruption, accompanied by a determination of the whole mass of blood inwards; a loaded condition of the great venous trunks of the abdominal, thoracic and cerebral cavities, with diminished power in the heart and arteries". (P. 11.)

As might be expected, passive congestion is the condition most prevalent, under the conditions just stated; and no matter what his previous disease in India may have been, the morbid condition now superadded proves a serious difficulty to the invalid. It is a very prevalent idea, that Indians are much less susceptible of cold during the first winter after their return than subsequently, as if they had in them, from long broiling, such a store of caloric

as kept them warm in spite of Jack Frost and his confederates. Mr. Martin states that this opinion is erroneous.

"My experience here in the last nine years would lead me to conclude, that if there really be any such immunity from cold during the first year of residence in England, as we hear spoken of so generally in India, it is enjoyed only by the healthy and robust. Numberless examples have satisfied me as to the truth of this observation: a dry or even frosty cold is well borne, comparatively, even by the enfeebled, tropical invalid; but the *damp* cold produces sensations of indescribable distress and depression in persons possessed of considerable powers of resistance.....The truth is, that in general the cold which a tropical invalid can bear without injury for a year or two after his return to Europe, is not of a low degree; and in extreme cases of disease, the in-door temperature carefully regulated during the winter and spring seasons is that alone which is safe to him. We cannot 'comfort' such a person 'with cold' as the Americans do their English customers with ice." (P. 12.)

"Anæmia," Mr. Martin informs us, "is common to fifteen out of twenty of tropical invalids on their return to Europe. In this morbid state, the paucity of blood corpuscles causes a diminished absorption of oxygen, a quicker circulation, and consequently a diminished animal heat. I have no doubt, also, that by long-continued exposure to tropical heats and malaria, the muscular system, including the heart, is relaxed and weakened, becoming irritable and defective in contractile power. I believe that to these circumstances we must refer the diminished power of the forces that circulate the blood, and the intermitting character of the pulse so common to old Indians." (P. 16.)

These observations are of importance in reference to the management of old residents in India. There are few physicians in this country who are practically acquainted with the temperament of such patients, but there are many who from circumstances may be called upon to prescribe for them. These hints are, therefore, of great value, assisting us in forming a diagnosis, and directing us in the application of our treatment. We regret that our space will not admit of our extracting the admirable and forcible description of anæmia as presented in these cases; nor can we attempt to do justice to the observations laid down for the management of this disease; for them we must refer to the work itself, and pass on to the second subject specially treated of.

Passive Congestion of the Liver. This is generally produced by the application of cold to the surface of the body, and not unfrequently by errors of diet. The organ is oppressed by an accumulation and stagnation of blood, while its function is paralysed; with all this we have also very frequently a weakened condition of the heart and arteries, and a diminished power of reaction. Much judgment is required in the treatment, for it often happens that we have to encounter a formidable disease in a debilitated person, who has perhaps been subjected to profuse bleeding, copious mercurials, and other heroic measures employed in the Tropics, where a few hours suffice for a disease to run its course unto death.

The natural result of great over-excitement and frequent disturbance of the hepatic function, is torpor of the liver. The cold and damp of this climate is especially likely to produce it; but there is another exciting cause too generally overlooked.

"It has," says the author, "been observed in Europe, that persons who have used mercury either in the liberal or rapid manner, or as a protracted alterative course, have frequently been afflicted subsequently with severe forms of hepatic disease. There can be no doubt, that through the repeated use of this mineral, even when necessarily exhibited, the hepatic function is inordinately stimulated, to be proportionately enfeebled thereafter. The action of mercury on the liver may be viewed as having a close analogy to

the primary excitement and subsequent exhaustion of the functions of the stomach, produced by dram drinking". (P. 45.)

We now come to a portion of the subject which Mr. Martin has made exclusively his own. Some fifty years ago, an officer arrived at Bombay from the interior, being on his way to England on account of enlarged liver: fortunately, he fell into the hands of Dr. Helenus Scott, who treated him after a peculiar manner, and his health became so speedily restored, that he was enabled to return to his troops and soon after to command them in a battle; that battle was Assaye, and that officer the Duke of Wellington. The treatment employed in his case was submersion in nitro-muriatic acid baths; a method which made some noise at the time, but fell into disuse, and so little was it appreciated, that in *Christison's Dispensatory*, Edition, 1842, it is thus spoken of: "It (nitro-muriatic acid) was introduced into the Dublin Pharmacopœia in 1826, in consequence of its having been at the time a fashionable remedy in the form of foot-bath for the treatment of syphiloid diseases and chronic diseases of the liver. It was strongly recommended for these purposes not long before by Mr. Scott of Bombay, and his recommendation brought it for a season into no little notoriety; but it is now, I believe, entirely abandoned". (P. 41.)

Happily for suffering humanity, the matter has been taken up by Mr. Martin, and rescued from the oblivion into which it had so undeservedly fallen. It is but justice to that gentleman to say, that he has worked the subject out with great talent, zeal, and diligence. He has fortified his positions, by bringing to their aid information derived from chemistry, physiology, and pathology, and has showed that this method of treatment is as sound in principle as efficacious in practice. "It is a very powerful remedy: it acts powerfully in promoting the depurative functions of the liver, kidneys, bowels, and skin. I have, therefore, during more than twenty years in India and England, used it in many of the chronic affections of the liver, functional and structural, believing it, on the ground of my experience, to be an agent of the first order of importance." (P. 48.)

It has long been a subject of surprise to us, that the endermic mode of administering medicines has been so little practised. Why, for instance, is not iron in solution more frequently introduced into the system through the medium of the skin, when it is found to constipate the bowels if taken by the mouth? Why is not colchicum more frequently administered in the same manner, when its use is indicated, and yet when there are objections to the ordinary mode of prescribing it? We are firmly of opinion, that medicinal baths are therapeutic agents of great power, and that they are, in this country, by no means appreciated as they deserve.

The baths prescribed by Mr. Martin are thus composed. Three parts of hydrochloric acid, two parts of nitric acid, and five parts of water, are first carefully mixed; of this, three ounces by measure are added to each gallon of water, and for a recumbent bath about seven gallons is requisite. It is, of course, used warm, and produces a sort of formication on the skin. If used twice daily, a diarrhœa usually takes place from the fourteenth to the thirtieth day, and sometimes earlier, and this indicates that its emulgent action has commenced. Having had some experience in its use, we can bear cordial testimony to its efficacy; we have seen a patient diminish in circumference over the ribs, *five inches* in two months, whilst under this treatment; we have seen colour brought into the cheeks, and life into the eyes, in a case where an enormous liver was complicated with lumbar abscess and scrofulous disease of the hip-joint. In another instance, a patient within our knowledge is now in the enjoyment of robust health, who more than a year ago was condemned, by some of the most eminent of our physicians, to a brief existence of perhaps a few months. This gentleman recovered under the care of Mr. Martin; and we gladly add our testimony, whatever may be its worth, to the efficacy of the nitromuriatic baths in hepatic disease.

The length of time during which they must be used, necessarily varies with each case; but two, or at the utmost four months, generally suffice to work a marvellous change. Amongst the valuable qualities of this therapeutic agent, is the fact of its influence not being in the least degree counteracted by opium. In the words of the author:

"We obtain, in short, from the use of the mineral acids in the treatment of chronic disease, all the remedial aids which can be obtained from mercury in the treatment of acute disease; and that without any of the injurious consequences that so frequently ensue from the exhibition of the last-named agent. Persons of anæmic or scrofulous habit are liable to serious injury from the use of mercury, whether given in large doses during many days or in alterative doses, during weeks or months. It is quite otherwise in respect to the acids, the most marked and lasting improvement of the general health being the ordinary result of their exhibition." (P. 57.)

Every page of these essays bears the impress of a superior mind, sound judgment, lucid views, and enlarged experience. The ground opened up by the author had been almost hopelessly abandoned; but it is now proved to be rich and fertile. Besides the Indian invalid, there are scattered throughout this land hundreds of individuals, who may indeed be said to have entered into the dark valley of the shadow of death. On them,—the victims of hepatic disease,—there now beams a bright star of hope: and we feel that in speaking thus strongly of the treatment advocated by Mr. Martin, we are simply discharging our duty. We may add that the value of the work is materially enhanced by the introduction of many highly interesting and instructive cases.

Atalectasis Pulmonum; or Closure of the Air-Cells of the Lungs in Children. By George A. Rees, M.D. pp. 42. London: 1850.

The term Atalectasis is derived by the author from ατελης, *imperfect*, and εκτασις, *expansion*: the word therefore ought to be Atelectasis.[1] It is employed to designate a peculiar condition of the lungs, to which the term carnification has sometimes been applied.

The author divides the affection into two forms; one, where it exists as a defect from the hour of birth, and the other, where it occurs as a disease after birth. In the first case, the lung never assumes any other than its fœtal condition; in the second, the disease is induced at various periods after birth. Dr. Rees states that he was the first to describe this second form in the *Medical Gazette* for January 1839.

The *pathognomonic symptom* of Atelectasis is an altered movement of the ribs in respiration; during the inspiratory effort, the ribs move inwards or backwards towards the mesial line of the trunk, instead of outwards as in ordinary respiration, thus diminishing, instead of increasing, the diameter of the cavity. In emaciated patients there is also another remarkable symptom, namely, an undue tumidity of the abdomen; for, in consequence of the altered condition of the thoracic parietes, the abdominal muscles lose, to a great extent, their power of compressing the viscera, and hence the intestines become distended with air, besides exhibiting the phenomena of venous congestion.

The post-mortem appearances in Atelectasis are a solidified condition of the lung, which does not crepitate on pressure, a flabby consistence, and a dark purple colour; a compact structure, and a specific gravity greater than water. But the most curious fact, and one which serves to distinguish Atelectasis from hepatization is, that in the first, the tissue may by inflation be made in a great measure to resume its natural healthy appearance; for in Atelectasis the tissue is only closed and the lung is collapsed, while in hepatization, the

[1] We write *Atelocheilia*, signifying an imperfect development of the lip, and *Ateloëncephalia*, an imperfect development of the brain.

result is due to interstitial deposit, and no attempt at inflation can be attended with success.

Dr. Rees attributes the disease in great measure to the rearing of children in unhealthy localities, and therefore proposes that the treatment should be chiefly of a hygienic nature. He says that it should consist in the removal of the patient (if this can be accomplished) to a healthy locality ; in a judicious attention to diet and regimen ; and also in the administration of such remedies as promote the action of the skin and kidneys, relieve congestion of the hepatic vessels, and at the same time give tone to the system. Dr. Rees gives several interesting cases in illustration of his views.

We consider this little work as a valuable contribution to modern pathology and practice. We entirely adopt the opinions of the author, and commend them, and also the whole subject, to the study of our readers, but particularly to those who, from being engaged in family practice, have a large proportion of their patients among infants and young children.

On the Identity or Non-Identity of Typhoid and Typhus Fevers. By William Jenner, M.D., Professor of Pathological Anatomy in University College, London. pp. 102. London : 1850.

On the Identity or Non-Identity or the Specific Cause of Typhoid, Typhus, and Relapsing Fever. By William Jenner, M.D. pp. 20. 1850.

Dr. Jenner has spent three years at the London Fever Hospital, in endeavouring to solve the problems involved in the titles of the above publications ; and we are doing only a simple act of justice to him, when we state, that whether his conclusions be generally admitted or not, it is impossible not to acknowledge the zeal, and uncommon ability with which he has pursued his investigations. The results of his laborious inquiries are now before the public ; and the two works, the names of which are above quoted, contain an epitome of his views. Dr. Jenner is not a theorist either upon etiology or treatment ; and while maintaining that the causes of Typhoid and of Typhus Fever are essentially distinct, he does not professs to have discovered what the cause of either really is. Upon the treatment of these affections, he does not say a word. Indeed, the whole object of his works is to draw a comparison between Typhoid and Typhus Fevers, and to prove their non-identity ; and as we have just remarked, he has acquitted himself in his self-imposed task with distinguished ability.

Dr. Jenner informs us, in his work on the *Identity or Non-Identity of Typhoid and Typhus Fever*, that he has made notes of nearly 1000 cases during his researches at the London Fever Hospital ; but he (very properly, we think) selects for publication only those cases which proved fatal, and of which he had the opportunity of making post-mortem examinations. The number of these fatal cases, in all of which the symptoms were observed during life, and in which examinations were made after death, amounted to sixty-six, which Dr. Jenner has divided into two groups ; in forty-three, there was no appreciable disease of Peyer's patches, and in the remaining twenty-three, those structures were manifestly in a morbid condition. The first class of cases, were instances of Typhus, and the second class, of Typhoid Fever. The work which stands first at the head of this article, contains an analysis of these sixty-six cases. The age, sex, previous health, general condition of body, size, and complexion of the patients, are all carefully noted and compared ; the duration of the disease and the nature of the accompanying eruptions are minutely recorded ; and a *catalogue raisonnée* of the symptoms during life, and of the appearances observed after death, makes up the chief bulk of the volume. It would be impossible for us to follow the author through all his investigations ; but we may give the following, as among the most interesting and important conclusions which he has drawn from his labours.

Dr. Jenner strongly maintains that Typhoid and Typhus Fever are diseases which have a totally different origin, and are developed in a different manner; and he considers that they are quite as distinct as measles is from scarlatina. The chief anatomical difference consists of the presence of disease of Peyer's patches in Typhoid Fever, and its absence in Typhus; and it was accordingly found, that while in the former fever these patches were always diseased, in every one of the forty-three cases of Typhus Fever there was no recent disease whatever.

The diagnosis of these affections during life may be satisfactorily made by an observation of the concomitant eruption. In Typhoid Fever, it consists of a number of rose spots, of a papular character, slightly elevated, never acuminated at the apex, never flat, but invariably rounded, of a bright rose colour, gradually fading away into the natural hue of the skin, and disappearing completely upon pressure. The eruption accompanying Typhus Fever, is called a mulberry rash by Dr. Jenner; this eruption is never papular, and consists of very slightly elevated spots, of a dusky pink colour. Instead of disappearing in two or three days, like the rose spots of Typhoid Fever, the mulberry rash soon undergoes a remarkable change; the spots become of a darker and more dingy colour, and they only fade on pressure; and after exhibiting these characters, they disappear in some cases. In others, however, they reach a third stage, and the spots change into true petechiæ, *i. e.*, spots presenting the following characters: a dusky crimson or purple colour, quite unaffected by pressure, a well-defined margin, and a total absence of elevation above the level of the cuticle. The usual situation of these spots is on the trunk and extremities, but occasionally they are limited to the trunk, and now and then they are observed on the face.

The *Tongue* is stated by Dr. Jenner to have exhibited a remarkably different appearance in Typhoid and Typhus Fever. It was much more frequently moist throughout the disease in Typhoid, than in Typhus Fever. When dry, it was often red, glazed, and fissured, in the former; but it rarely exhibited these characters in the latter. In Typhoid Fever, when the tongue was brown, its hue was of a yellowish-brown, instead of a blackish-brown. "The small dry tongue, with red tip and edges, smooth, with pale brownish-yellow fur, fissured, the surface seen between the fissures being deep red, may be considered differentially, as a diagnostic sign of Typhoid Fever."

In the treatise on the *Identity or Non-Identity of the Specific Cause of Typhoid, Typhus, and Relapsing Fever*, Dr. Jenner draws an analogy between these diseases and small-pox, scarlatina, and measles; and he maintains, that just as the three last diseases, while presenting certain characters in common, are nevertheless essentially distinct in their specific causes, so the three fevers are characterized by differences equally well marked. The rose spots observed during life, and the presence of disease in Peyer's patches seen after death, are peculiar to, and absolutely diagnostic of, Typhoid Fever: the mulberry rash, often passing into true petechiæ, and the absence of disease in the agminated glands, are characteristic of Typhus; while the Relapsing Fever is distinguished by the recurrence of the symptoms after apparent convalescence.

In answer to the view which has been taken, that Typhoid and Typhus Fever are merely modifications of the same disease, induced by variations of the epidemic constitution, Dr. Jenner maintains that his experience is in direct opposition to such a statement. "I may remark," he says, "that during three years' attentive watching of nearly all the cases admitted into the London Fever Hospital, in which time there have been epidemics of Relapsing Fever, Typhus fever, and Cholera, and, consequently, according to those whose opinions I am here examining, as many changes in epidemic constitution, I have seen no alteration in the general or particular symptoms of either Typhus or Typhoid Fevers, or the lesions observed after death from either, *i. e.*, from November 1846, to November 1849. The cases of Typhoid

Fever, which disease is rarely absent for a fortnight from the wards of the hospital, preserved their symptoms unchanged, and presented the same lesions, whatever the epidemic constitution that prevailed: the same is true of Typhus Fever. Cases of the latter disease are also rarely absent from the wards of the same institution."

Dr. Jenner's work is not only a valuable contribution to practical medicine, but is truly a model to all pathological writers. The conclusions are drawn only after the most careful investigation of facts; and the symptoms and post-mortem appearances are detailed with a minute accuracy, which, though it may appear tedious to the superficial reader, is, in our opinion, absolutely necessary, not only in the investigation of the nature of fevers, but of the history of diseases in general. The habits of the present day have produced much false philosophy in the art and science of medicine; and we hail with pleasure the appearance of a work like that of Dr. Jenner, which draws conclusions only from those true sources which are the foundations of rational medicine.

La Homeopatía, ó Farmacologia Analogo-Infinitesimal, ante el Criterio y el Sentido Comun. Lecciones de Refutacion de la Doctrina de Hahnemann, esplicadas en la Facultad de Medicina de la Universidad de Madrid al concluir el Curso de 1849 a 1850. Por Don Tomas de Corral y Ona, Doctor en Medicina y Cirujia, etc. pp. 258. Madrid: 1850.

[Homœopathy, or Analogo-Infinitesimal Pharmacology, tested by Reason and Common Sense: being Lectures delivered in the University of Madrid, during the session 1849-50. By Dr. Tomas de Corral y Ona.]

After some preliminary remarks on the antipathic, alopathic, and homœopathic methods of treating disease, the author examines the *Organon* of Hahnemann, which he shews to possess none of the characters of order, method, or harmony, which its name might lead one to expect; for "the principles are mixed up with the accessory ideas; the antecedent often follows the consequent; the primary ideas sometimes do not afford a clue to those which follow; and his principles, foundations, and chief ideas, seem as if they had been rained from the sky, without preparation or announcement." Having disposed of the *Organon*, he examines the homœopathic law, *similia similibus curantur*. In the theogony of Hindostan, Egypt, and Greece, in logic, natural philosophy, mathematics, and chemistry, the operation of two opposing forces has been recognised from the earliest ages; and the knowledge of these forces is treated of by the author as a system of *dualism of forces (dualismo virtual)*. The homœopathic law is in direct contradiction to this universal principle; and it cannot be applied to the human body, for there the operation of the law of contraries, is evident both in the physiological and in the pathological states, and is the foundation of rational treatment.

The system of infinitesimal doses is next judged at the tribunal of common sense; for the author very truly says, that it is impossible to reason with those who will gravely maintain, that, if common salt be homœopathically diluted, the taste ought to be felt as the dilution is increased; or that the power of a substance increases in the direct ratio of its diminution.

It may be said by some, that it is beneath the dignity of a University Professor to elaborately refute, *ex cathedrâ*, the rank nonsense of homœopathy; and if we were sure he had to teach a body of young men, well educated, and with well disciplined minds, we would subscribe to this opinion. But in Spain, the preliminary education of the medical profession, though not so much neglected as it is in this country, is still so lamentably deficient as fully to justify the anti-homœopathic lectures of Dr. de Corral y Oña. It is certainly more honourable for the University of Madrid to have one of its professors ably exposing the fallacies of homœopathy, than it is for another university, nearer home, to tolerate the odious scandal of a globulist in the chair of Pathology!

CRITICAL DIGEST OF THE BRITISH AND FOREIGN MEDICAL JOURNALS.

PRACTICE OF MEDICINE AND PATHOLOGY.

ABORTIVE TREATMENT OF VARIOLA BY THE APPLICATION OF COLLODION.

Collodion has been found useful in arresting the course of traumatic erysipelas and of herpes : and the *Bulletin Général de Thérapeutique* for Oct. 30, 1850, contains an account of a case occurring in the practice of M. Aran, which seems to shew it to be an efficient agent in producing abortion of the variolous pustules. We abridge the account given.

Case. A young man, aged 19, was admitted into the Hôpital Bon-Secours, in Paris, with confluent small-pox in an early stage. The face was thickly covered with small pustules, and there was already intense swelling and redness. The fever was very moderate. M. Aran applied a layer of Collodion over the face, to produce abortion of the pustules. In two days, the lips, and lobes of the ears, which had not been covered, shewed well-developed pustules ; while scarcely anything could be seen through the Collodion, and, on raising it, the pustules were found arrested. The Collodion having become accidentally removed in parts, the exposed portions of the face, in fifteen or eighteen hours, presented well-developed pustules. It was again applied, and constantly watched, to prevent the patient from tearing it off during his delirium. On the eighth or ninth day from the first application of the Collodion, it began to fall from the eyebrows, leaving them of a rose colour, without any scars. On the following days, the Collodion fell from the other parts of the face, together with the desquamated epidermis. The skin of the face appeared as if it had undergone desquamation after erysipelas. On the other parts of the body, the eruption, which had been very confluent, had left numerous spots and scars. The general condition of the patient was most satisfactory.

Collodion seems to act as a mechanical constringent of the tissues. This view is supported by the fact that, in the latter days of the suppurative stage, the pustules were seen to appear at the edges of the layer, and to raise it, while nothing of the kind was observed elsewhere. M. Vallcix has also used the same remedy in a case of *variola discreta*, with perfect success ; and in a case of non-confluent small-pox, M. Aran has procured the abortion of almost all the pustules on the face, so as to render it extremely difficult to find a mark.

BRUCINE IN LEAD-PALSY.

As an internal remedy in lead-palsy, Brucine possesses advantages over strychnine, as it is capable of being safely administered in larger doses. M. Bricheteau gives it at first in doses of two or three centigrammes (about one-third to half a grain) daily, and sometimes raises the quantity to eighty centigrammes ; but this is rarely necessary. At the dose of from ten to fifteen centigrammes, it produces slight twitchings, with a creeping sensation in the limbs. When the dose is raised to twenty or twenty-five centigrammes, the twitchings become more powerful, and begin to be accompanied by stiffness of the limbs, which are put in a state of forced extension. When the patients are still, the convulsive movements are slight : but if they move in bed, the twitchings and tetanic symptoms appear. When they walk, their limbs become stiff, and they fall forward, if not supported. These symptoms are not accompanied by disturbance of the intellect, nor by headache.

In a case lately under the care of M. Bricheteau, of paralysis of the extensors of the thumbs and fingers, the good effects of this treatment were complete. The paralysis was complete ; but, in a month, the patient was able to raise the thumbs, and ultimately made a perfect recovery. (Abridged from *Bulletin Général de Thérapeutique* of October 15, 1850.)

CHLOROFORM IN LEAD-COLIC.

Dr. Aran has published, in the *Bulletin Général de Thérapeutique* for October 15, 1850, the results of his experience in the use of Chloroform as a remedy in Lead-Colic. His observations are confirmatory of the opinions which we expressed at page 285 of this Journal, for March 1850, in referring to the paper of Dr. Blanchet in the *Journal de Chimie Médicale.* The following are the conclusions at which Dr. Aran has arrived.

There can be no doubt as to the possibility of very soon curing Lead-Colic, by the internal and external use of Chloroform. The advantages of this treatment are striking. Lead-Colic is eminently a painful affection ; Chloroform removes the pain. The disease is probably dependent on intestinal spasm, which tends to produce the characteristic obstinate constipation ; Chloroform calms the spasms. It does not, indeed, cause the lead to be evacuated from the system ; but, by the employment of sulphur and alkaline baths, the skin is freed from the metal ; and the same effect is produced on the intestines by enemata. No inconvenience is likely to arise, when the evacuations are re-established slowly and with difficulty, from the use, for some days, of castor-oil or some other mild purgative. Drastic purgatives frequently increase the colic, and even produce vomiting, when given before the pains are calmed and the evacuations re-established. Chloroform, applied principally externally, immediately calms the pains, and facilitates the use of purgatives, if it be found necessary to employ them.

The mode of external application, adopted by Dr. Aran, is to pour from one to two drachms of Chloroform on a wet cloth, and keep it applied to the abdomen for a quarter or half-an-hour. He also gives it in mixture ; and in enemata, preceded by a common injection. It is on the local application, however, that he seems to place most reliance. The enemata have sometimes appeared to increase the pain.

CASE OF SOFTENING OF CEREBRUM AND CEREBELLUM : FATTY DEGENERATION OF HEART : TUBERCULAR ABSCESSES IN LUNGS.

Dr. J. D. Brown of Strood, Kent, relates the following case in the *Medical Gazette* for December 13, 1850.

Case. E. K., aged 39, had suffered for five years from occasional attacks of giddiness, pain in the head, and sickness, with numbness in one of the lower limbs. In December 1849 and January 1850, she laboured under symptoms of chronic inflammation of the brain, which appeared when she had scarcely recovered from a miscarriage. Her memory was impaired : there was paralysis of the left lower extremity, with weakness of the right leg ; there was occasional rigidity of the muscles of the lower limbs. Emaciation progressed to a considerable extent. On the 7th June, she was attacked with bronchitis, but recovered. On the 19th, she was seized with a paroxysm of breathlessness, which returned several times ; and she died in one of these paroxysms on the 29th. Throughout this day and the preceding night, she fancied she saw deceased persons. Her consciousness never failed, though she had a dull, vacant aspect. She said that there was a sensation of "squashing" in the back part of the head, and that, when erect, she felt as if about to fall forward.

Post-mortem Examination, forty-two hours after death. The skull was dense, and greatly thickened, particularly anteriorly and laterally. There were about three ounces of serum beneath the membranes ; the ventricles contained but little fluid. The vessels of the *pia mater* were dilated : there was no disease in the arteries at the base of the brain. The cerebral convolutions were healthy, and moderately firm. There was white softening of the corpus callosum ; the fornix and its crura were almost destroyed, and

the peduncles of the pineal gland were completely removed by ramollissement: the crura cerebri in the vicinity of the pons Varolii, the superior vermiform process, and the upper surface of the cerebellar hemispheres, were in a softened state. The medulla oblongata was sound. The heart presented an extreme degree of fatty degeneration. The lungs were emphysematous anteriorly, and contained numerous tubercular abscesses, filled with thin pus, and having no communication with the bronchi. The liver was large and fatty: the spleen extremely soft; and the kidneys also much softened.

COD-LIVER OIL IN JAIL-CACHEXIA.

Mr. Caleb Rose of Swaffham, Norfolk, has published, in the *Provincial Medical and Surgical Journal* for Nov. 27, 1850, some remarks on the scrofulous Cachexia, common among prisoners, which he believes to differ from the ordinary forms of scrofula. The symptoms of the disease are these: The man looks paler and thinner than usual; is very much depressed in spirits; has no appetite; sleeps badly; and has profuse night-sweats; there is slight diarrhœa; the pulse is quick, irritable, and feeble. The cervical glands are always more or less enlarged, and continue to enlarge very rapidly. In five years, three died in prison, two of very rapid phthisis, the third of tubercular peritonitis. The others who were seriously affected, were discharged before their proper time, and recovered speedily after their liberation. Those who suffered less were carried on to the end of their term of imprisonment by care and indulgence. Rather more than two years since, the use of Cod-liver oil was commenced, and with the best effects. The two men who first took the oil had the cervical glands much enlarged (in one of them suppurating) and, as they had still to remain some months longer in prison, it was thought that they must have been discharged before the end of their term; however, after taking the oil a month, they improved steadily, and eventually left the prison at their proper time, in as good health as when they entered it. Since these two cases, there have not been any so severe, as the oil has been administered in good time to those presenting indications of scrofula; they have gained flesh and strength, and their health has apparently been entirely restored.

ADMINISTRATION OF IRON IN FOOD.

M. Martens has lately read an essay before the Belgian Academy of Medicine, on Ferruginous Medicines. Among his conclusions, as published in the *Gazette Médicale de Paris* for 30th November, we find the following:

"Wheaten bread may be rendered much more nutritive" for chlorotic patients, "by adding a small quantity of sulphate of iron. In this way alone, it can be capable of forming a substitute for meat."

In the discussion, it was suggested that the same method of medication would be beneficial to patients recovering from acute diseases, especially when the system was not yet able to bear an animal diet. The idea is good: and would be easy of application.

SURGERY.

STATISTICS OF AMPUTATIONS OF LARGE LIMBS IN THE MASSACHUSETTS GENERAL HOSPITAL.

Dr. George Hayward, one of the surgeons to the Massachusetts General Hospital, has published in the *Boston Medical and Surgical Journal* for October 2, 1850, a valuable statistical account of all the Amputations of Large Limbs which have been performed in that institution from January 1822 to

January 1850. He gives two tables; the first comprising 67 cases, extending from January 1822 to January 1840; the second, including 74 cases, occurring from the latter period to January 1850. The following is a summary of the principal facts contained in the tables.

The entire number of patients was 141, on whom 146 operations were performed.[1] They may be thus arranged:

Seat of Operation.	Cause.		Rec.	Died.	Per Cent. Rec.	Per Cent. Died.
Above Knee, 69	Disease	49	40	9	81·6	18·4
	Injury	20	10	10	50·0	50·0
Below Knee, 50	Disease	24	23	1	95·8	4·2
	Injury	26	17	9	65.4	34·6
Above Elbow, 11	Disease	7	7	0	100·0	0 0
	Injury	4	3	1	75·0	25·0
Below Elbow, 11	Disease	6	6	0	100·0	0 0
	Injury	5	3	2	60·0	40·0

It thus appears, that 85 patients had their limbs removed in consequence of disease, of whom 10, or 11·76 per cent., died; and 56 in consequence of injury, of whom 22, or 39·3 per cent., died.

The ages of the patients were as follows:

Under 20 years of age,	26,	of whom 4 died.
Between 20 and 30	56,	" 11 died.
" 30 and 40	28,	" 10 died.
" 40 and 50	18,	" 5 died.
" 50 and 60	7,	" 1 died.
" 60 and 70	4,	" 1 died.
Over 70	2,	" 0 died.
	141	32

In the second table, it is stated whether each operation was performed by flap or by the circular method.

	By Flap.	Circular.
Above Knee	20	15
Below Knee	14	12
Above Elbow	2	5
Below Elbow	1	5
	37	37

The following are some of the remarks made by Dr. Hayward:

The result of amputations is much influenced, not only by the age and constitution of the patient, and the disease or injury for which the operation is performed, but also by the period at which it is done. In cases of chronic disease of the limbs, the operation is often deferred till it is too late. But an operation is often resorted to in recent injuries, earlier than it should be. If the injury be not so serious as to cause almost immediate death, reaction usually comes on, with proper management, in a few hours; and then, if an operation be necessary, it can be done with a much greater prospect of success than during the stage of prostration.

In rail-road accidents, there is a great tendency of the parts in the neighbourhood of the injury to slough after the operation. These accidents, when sufficiently severe to require amputation, are usually caused by a wheel of an

[1] In two of the cases of amputation above the knee, the other leg was also removed below; both died. In two, both legs were removed below the knee, and both patients recovered; in one case, one arm was removed above the elbow, and the other below: this patient also recovered.

engine or railway car passing over the limb, and generally producing a compound and comminated fracture of the worst kind. If the operation be performed in the immediate neighbourhood of the injury, the parts, however apparently sound at the time, will in most cases slough to a greater or less extent, so as to require the removal of the protruding portion of bone at a subsequent period. The operation should be done at a greater distance from the injury, than is usual in ordinary cases of accident. The condition of the parts resembles that which is described by military surgeons under the name of local asphyxia, as occurring from gun-shot wounds. It is a state of suspended animation, differing from death only in the fact, that the power of resisting decomposition is for a time retained; but the debilitating effect of an operation is very sure to destroy this.

Forty-eight of the patients inhaled some anæsthetic agent, generally sulphuric or chloric ether. It was at this hospital that these agents were first successfully employed in general operative surgery; and so satisfactory have been the results, that no operation of any importance is now performed there without the previous use of these means. No fatal effects have followed their administration, nor has any serious ill consequence ever ensued.

CASE OF FIBROUS POLYPUS, BY PROFESSOR SYME.

The following is a very interesting case, which appears to have been at first mistaken for some more malignant disease; probably for fungus hæmatodes. Yet we think that a longer period than three months would be necessary, to decide whether the unfavourable prognosis made in the first instance were correct or not. It is reported by PROFESSOR SYME in the *Edinburgh Monthly Journal* for November 1850.

CASE. Lord —— consulted Mr. Syme on 29th June, 1850. He had, in consequence of a fall from horseback three years previously, sustained an injury of the nose, followed at different times by profuse bleeding, and complete obstruction of the nasal passages, with loss of smell and taste. Small portions of a polypous growth had been extracted; and repeated attempts at extraction were subsequently made, without success. On consultation, in London, it was decided that any operative interference was ineligible; that the case did not admit of any beneficial interference; and a certain and not remotely fatal termination of his complaint was predicted. On putting his finger into the pharynx, behind the soft palate, Mr. Syme recognized a polypous growth, extending from the nose backwards. On re-examination, both nostrils were found completely obstructed, both in inspiration and expiration. Nothing was felt in the left one: but, in the right, a small portion of polypus, similar to the ordinary mucous growth, was perceptible. Pressure on the pharyngeal tumour excited profuse bleeding, more from the nose than the throat. At all times, there was a copious distillation from the nostril of a slightly coloured fluid, which could only be removed by a wringing sort of action; and at night the bed-clothes were soiled by it. The morbid growth was speedily extracted, in one mass, through the nose, with the small polypus forceps introduced into the right nostril, aided by the fore and middle fingers of the left hand, inserted behind the soft palate. The operation was in every respect successful, and three months had passed, without any threatening of a relapse.

The polypus consisted principally of a reddish fibrous substance, extremely firm, except where it descended into the pharynx, where it was more friable. It agreed in all respects with the "fibrous polypus" of M. Dupuytren, viz.. in firm consistence at the central or original part; in a tendency to soft degeneration at the circumference; in a great disposition to bleed; in a strong adhesion to the surface of the bone; and in the absence of any malignant action after its complete avulsion. The source of the complaint in Lord ———'s case probably existed long before the accident to which it was attributed.

FRACTURE OF THE OS CALCIS.

Dr. Uhde reports the following case in the *Mittheilungen über die in der chirurg. Klinik zu Braunschweig vorgekommenen Krankheiten und Operationen.*

Case. C. W., a journeyman carpenter, æt. 40, was admitted into hospital on the 20th November, 1844. Four hours before admission, he had fallen from a ladder a height of twenty feet, on a floor covered with sand as high as a shoe. His heels first came to the ground. He complained of very severe pain in the heel of the right foot. He said that, on reaching the ground, he heard a cracking sound in the foot ; and asserted that he could neither walk with, nor extend it. There was also pain in the right calf. On the back of the foot, there was a hot, moderately raised swelling. On the lower surface, and on the heel, no change of form was observable. When the heel was grasped in one hand, and the foot pressed against it with the other, mobility and crepitation were readily perceived. The anterior third of the Os Calcis was fractured from above downwards. The examination gave extreme pain to the patient.

Rest and cold applications, with Dover's powder at night, were the only means employed till the 27th. On this day, a dextrine bandage was applied, which remained on until the 21st December. On the 27th of this month, the patient was enabled to leave the hospital on crutches ; and in the middle of January 1845, he was first enabled to walk without lameness.

It could not be discovered whether the bone united by callus or by ligament. The right foot was for a year subject to swelling after exertion. The degree of weakness, which Metzger asserts to attend this affection, was, in May 1848, no longer observable.

DR. DOUGLAS MACLAGAN ON THE EXTIRPATION OF ERECTILE TUMOURS BY CAUTERY.

In his *Lectures on General Therapeutics*, Dr. Douglas Maclagan makes the following remarks : " These Erectile Tumours, which consist essentially of a congeries of enlarged blood-vessels, are commonly treated by ligature ; but this causes a good deal of suffering, and often much constitutional irritation, before the strangulated mass finally separates. The method of applying the cautery is to pass a large red-hot surgical needle, which may be readily heated by a gas-flame, once or twice through the base of the tumour ; and the object is to cause effusion of lymph, and thus to alter the structure of the tumour, and arrest its growth. There are other means of effecting this object ; but I mention this as one which, though noticed in surgical works, has not received that attention which I think it deserves." [*Edin. Monthly Journal*, November 1850.]

DR D. MACLAGAN ON THE APPLICATION OF CAUSTIC TO THE HÆMORRHAGE FROM LEECH-BITES.

The following is the substance of some remarks made by Dr. D. Maclagan on the arresting of Hæmorrhage from Leech-Bites.

In cauterizing to arrest bleeding from a cavity, as a leech-bite, or the alveolus of the jaw, it is obviously essential that the caustic or cautery penetrate to the very bottom of the wound, which is probably the chief source of the hæmorrhage. In leech-bites in children, Dr. Maclagan has seen a piece of caustic cause much pain, and yet leave the bleeding artery as active as ever, simply because it was too thick to reach the bottom. He has often, therefore, had recourse to a simple and ingenious plan recommended by the late Dr. James Hunter ; viz., to powder a piece of nitrate of silver, heat the point of a silver probe in a candle, and dip it into the powder ; it thus becomes crusted with the nitrate, and forms a fine button of caustic, which

will easily reach the bottom of any such wound. When the bleeding has been stopped, we must beware of injudiciously meddling with the part: the occlusion of the divided vessels is as yet only temporary, and may be easily overcome. [*Edinburgh Monthly Journal of Medical Science*, November 1850.]

DISLOCATION OF THE FIFTH CERVICAL VERTEBRA: DEATH IN ONE HUNDRED AND TEN DAYS.

Case. On Dec. 16, 1848, Mr. I. Mansfield, a muscular, healthy man, æt. 28, of strictly temperate habits, fell backwards from a spring wagon in which he was riding slowly in an erect position, and struck the ground. He was found instantly, lying on his side, with his body and legs flexed, and complaining of great pain in the back of his neck. With some assistance, he walked to a house about four rods distant, and then lost all use of his lower extremities, and nearly all power of using his arms and hands. He had constant pain over the fifth and sixth cervical vertebræ, increased by the slightest motion of his head. The pain was greater in the left shoulder and arm than in the right.

From the seat of the pain, and the tumefaction, from the entire loss of sensibility below the fifth cervical vertebra, as well as from paralysis of the intercostal nerves, and respiration being performed only by the diaphragm, it was evident that the force of the fall was received on the spinous processes of the fifth and sixth cervical vertebræ. No evidence was discovered of fracture or displacement. There was considerable general excitement; tongue coated; pulse 100; skin hot; great thirst. Treatment: venesection; leeching; cathartics and blisters. The urine was high coloured, and exhaled a strong ammoniacal odour. The catheter was required twice daily.

January 10th. Pulse 90; appetite improving; unable to lie on either side; often declared he would much rather die than be turned; dreaded the slightest motion of his body or head; had almost constant pain in his shoulders and arms; and often, both night and day, screamed out for the attendants to move his arms, which mitigated the pain, but only for a short time.

February. As his position could not be changed, large ulcers formed. Tongue clean; pulse 90; appetite good: sleep much broken; ulcers dressed with antiseptics; totally unconscious of dejections, which took place generally once a day with great regularity. Took strychnia. Shocks from the galvanic battery seemed for awhile to arouse twitching and considerable feeling in his legs, arms, and hands; involuntary passage of urine.

March. Evidently more feeble; ulcerations rapidly extending, exposing the middle of the sacrum and left tuberosity of the ischium, discharging copiously very fœtid matter. The ulcers were dressed with cotton, dipped in dilute nitric acid. Tonics and stimulants were taken. Could now move his head slightly to either side. Abdomen tympanitic. Had slight and transient sensation on the skin of his feet, on the sides of his thorax, and on the skin.

April. Emaciated rapidly; high fever; pulse 105; appetite gone; powers failing; occasional vomiting; intense burning heat through the abdomen. 6th. The ulcers had laid bare the three upper lumbar vertebræ, and discharged freely. Pulse 140; copious perspiration; countenance cadaverous; cheeks and eyes sunk; suffered great pain; and seemed to breathe with pain; articulation distinct; mind clear and composed; aware of his critical situation. Inhaled a few drops of chloroform every few minutes, just enough to overcome the sensation of pain, and leave the mind unaffected. 7th. He died.

Autopsy eighteen hours after death; by Dr. Nye and Dr. J. B. Holder. Muscles thickened over lower cervical vertebræ. Fracture of the left bifurcation of the spinous process of the fifth cervical vertebra; the fifth cervical vertebra dislocated anteriorly full two-thirds of the diameter of the spinal canal; fracture of one half of left articular process of sixth cervical vertebra, leaving the right articular process entire, but covered with ossific deposit. A thin lamina of bone deposited around the middle of the body of the sixth

cervical vertebra, extending, at an angle of forty-five degrees, nearly to the anterior inferior edge of the fifth, which overhung it. The lateral articular processes firmly united by bony union. Fracture of one-half of the right articular process of the sixth, allowed the right side of the fifth to project forwards farther than the left side. Short spiculæ of bone, turning inwards on the medulla, from the superior edge of the posterior part of the sixth cervical, and from the inferior edge of the fifth. The cavity of the medulla was diminished two-thirds of its diameter, and contained large clots of coagulable lymph external to the membranes. Medulla much softened for the space of one and a half inches; and membranes soft and thickened.

It is a well-known fact, that displacements of the fifth cervical vertebra are generally suddenly fatal. Sir A. Cooper says, the patients die in from three to seven days, according as the injury is seated in the fifth, sixth, or seventh cervical vertebra.

The reporter (Dr. James M. Nye) asks, may we not reasonably expect that, in cases of spinal displacements, if not in fractures (if the diagnosis is correctly made out), some means may be discovered for their successful reduction? Etherization, too, would probably, he adds, be auxiliary to such means, as in other surgical operations. [*Boston Med. and Surg. Journal*, 1849.]

OBSTETRICS.

AMPUTATION OF THE ARM NOT NECESSARY, WHEN THIS LIMB PROTRUDES IN SHOULDER-PRESENTATIONS.

M. Chailly-Honoré has published a valuable paper, on the above subject, in the *Bulletin Général de Thérapeutique* for July 15, 1850. We give a slightly abridged translation, with copies of the wood-cuts by which the memoir is illustrated.

The protrusion of the arm is not a complication of shoulder presentations: it is an epiphenomenon, which never affords any obstacle to delivery. The accoucheur is, therefore, never authorised to amputate this limb; and its presence does not impede the operation of turning. This proposition is supported by the following case, which lately occurred under M. Marrotte, in the Hôpital Ste. Marguérite.

Case. A woman named D., entered that establishment to be confined. The membranes had been ruptured four or five hours before the *interne* examined her. Discovering a presentation of the right-arm, he attempted to turn, but without success. M. Chailly-Honoré, being called to the case by M. Marrotte, found the arm very swollen, and livid; he fastened a string to it, which he caused to be held loosely on the outside, then turned the child, and completed delivery in a few minutes. Although fifteen hours had elapsed since the rupture of the membranes, the child was alive.

Although a contrary opinion has been maintained, it is certain, that the protruded arm can never be an obstacle to turning: and when (which seldom happens) this cannot be effected, the impediment does not arise from the protrusion of the limb; on the contrary, it facilitates the diagnosis, permits the position of the child to be ascertained, and renders extraction more easy, after the feet have been brought down. The real obstacle has been proved to exist in the energetic action of the uterus.

In some cases, nature completes the labour by *spontaneous evolution*. This, which is much better known than spontaneous version, is accomplished in shoulder presentations, almost exactly under the same laws as all other cases of spontaneous expulsion; and the analogy is more perfect, as the infant approaches to the full size. At the same time, this proceeding becomes more difficult, and more dangerous for the mother and child. To illustrate this form of delivery, we may suppose a case of presentation of the right shoulder, the position being the *right cephalo-iliac*.

Immediately after the rupture of the membranes, the parts are diminished in volume. This period is analogous to that of flexion in presentation of the vertex, and to deflexion in that of the face. The shoulder then gradually passes into the pelvis: and, as it does so, the fœtus, by a rotary movement, places the head on the horizontal branch of the left pubic bone, and the shoulder under the pubic arch. The arm then appears outside the vulva: but sometimes it presents before this period. The flank of the fœtus is now pushed into the pelvic cavity, gliding over the right sacro-iliac symphysis, while the shoulder remains immoveable. The pelvic extremity follows the same direction as the side. At last, the perinæum bulges, and the lateral and upper parts of the chest, the hip, and the lower limb, appear at the anterior commissure. As these parts are disengaged, the head and left arm descend, and are very soon expelled, generally without any rotation of the head. In fact, the maternal parts have just been too much distended. (See Figs. 1, 2, 3, 4.)

Fig. 1. Spontaneous evolution: presentation of arm.

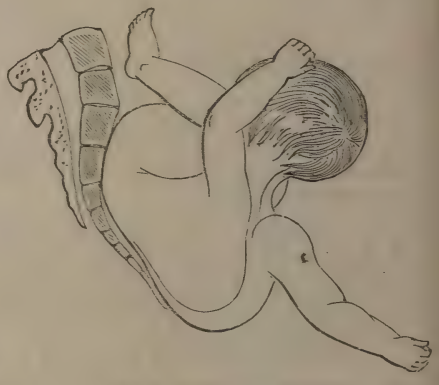

Fig. 2. Spontaneous evolution.

Fig. 3. Spontaneous evolution.

Fig. 4. Spontaneous evolution.

When the fœtus looks anteriorly, expulsion occurs in the same manner; but it is here more easy to observe the regularity with which rotation is accomplished, by which, in all presentations, the posterior part of the fœtus must be turned forward. As the fœtus escapes from the vulva, it performs a movement of torsion, which brings its back to the front part of the mother. (Fig. 5.) M. Paul Dubois was the first to determine the existence of this phenomenon. A number of cases of this kind have been reported by MM. Chailly-Honoré, Velpeau, and Denman.

Fig. 5. Spontaneous rotation.

In the majority of labours at the full period, this expulsion cannot be effected, when the pelvis and the fœtus are of normal size: the mother will generally perish before labour is completed, if not assisted by art. The dangers to which both mother and child are exposed are easily explained. The length of the labour, and the pressure to which the fœtus is subjected, almost always prove fatal to it; and the forced passage of the child bruises and lacerates, more or less, the maternal organs. Moreover, the horrible and continued pain attendant on such a delivery, produces a constitutional shock from which the woman cannot recover. The unfavourable prognosis attending on this form of labour militates against the practice of Denman, who left most of these cases to nature. In 137 cases of spontaneous evolution, collected by M. Velpeau, 125 infants died. Many women have perished before delivery was completed, or soon after; and many have continued to live, in a state more deplorable than death itself. Before the full period of gestation, spontaneous evolution may be safe, both for mother and child, especially if the pelvis be capacious, the uterine contractions very powerful, the fœtus small, and the parts offering little resistance. As may be supposed, it is very difficult in primiparæ.

As, then, spontaneous evolution in these cases is only effected under exceptional circumstances, and almost always compromises the life of the child, and frequently that of the mother, the *accoucheur must never be content with being a mere spectator in such cases.* He must render his aid before the energetic action of the uterus has placed insurmountable obstacles in the way of turning. Should traction be exerted on the arm? This can produce no good result: even when the infant is very small, it would be fatal to it; and would, moreover, endanger the integrity of the maternal organs. Must the arm be replaced? The resistance of the uterus renders this impossible; and the attempts to overcome the action of the uterus are dangerous to the mother: besides, the reduction would be useless. On the contrary, it is an advantage to have the arm disengaged: it facilitates, as has been already said, the extraction of the trunk.

Those authors who have advised amputation of the arm, found their observations on the alleged facility with which turning has been effected after this operation has been performed. The following two cases will show reasons for entertaining a contrary opinion.

Case I. Dr. Lebrun, of Argenteuil, called M. Chailly-Honoré to deliver a woman. Two accoucheurs had previously for two days made repeated and unsuccessful attempts at turning. This was now effected in a quarter of an hour, without pain to the patient, and with great facility ; the explanation of which was the following. As long as the woman preserved her strength, the uterus had been able to react against the hands of the operators ; but at last she was in such a state of exhaustion, that the uterus was relaxed. The approach of death had brought on such a complete state of collapse, that the hand could be passed into the uterus ; whereas, a few hours before, this was impossible. *This is the whole explanation.* In fact, supposing that the arm had been removed, the ease with which the hand was introduced, would certainly have been attributed to this operation. It is such cases as this, which, being misinterpreted, have led into error.

Case II. An obstetric practitioner was called to assist in turning in a similar case. Finding it difficult to introduce the hand, he amputated the child's arm, without examining whether it were alive or not. He was at least not more successful in his attempts after the operation ; for, instead of a foot, the other arm, lying near the orifice, was brought down. M. Chailly-Honoré was now called ; and proceeded to deliver the woman by placing her on her knees and elbows. This position, for a knowledge of which he is indebted to M. Kilian, of Bonn, permits the feet to be reached with the greatest ease (see Fig. 6). When the woman is in this position, the hand, unless the

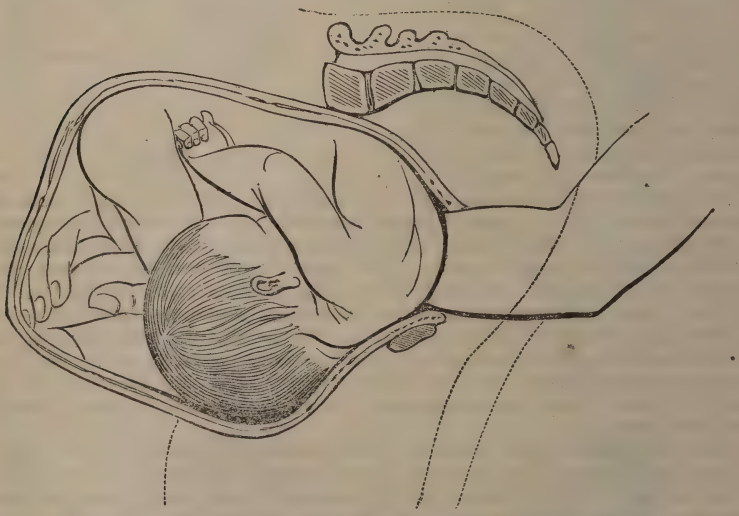

Fig. 7. Introduction of the hand, the patient being on her knees and elbows.

action of the uterus be too energetic, passes directly towards the fundus of the organ. But when the woman is on her back, the hand and arm have to be bent forwards in order to find the feet ; and thus the attitude compromises the success of the operation. In this case, with the change of position of he patient, turning was easily accomplished, the second arm still remaining outside the vagina. If it had been amputated, the success would have been ascribed to this operation.

M. Chailly-Honoré has observed many similar instances ; and he has been induced now to notice this subject at some length, as some of the cases have come under his notice since the publication of his work.

Far from impeding the operator, the arm even renders his manipulations

more simple and easy. It can scarcely be supposed to be otherwise; for the arm, however swollen, is not large enough to prevent the hand from passing into the uterine orifice. The only cause which can render turning impossible, is uterine contraction: and this is always more or less energetic when the arm is disengaged; being, in fact, the cause of the latter phenomenon.

PROFESSOR SIMPSON ON PUERPERAL AND SURGICAL FEVER.

The following is an abridgment of a paper published by PROFESSOR J. Y. SIMPSON, in the *Edinburgh Monthly Journal of Medical Science* for November 1850.

Nearly three thousand mothers die in child-bed, every year, in England and Wales, the great majority from Puerperal Fever.[1] Many subjects of surgical operations die, however well the operations may be performed. Among every hundred cases of amputation of the limbs, about thirty die. In four thousand nine hundred and thirty-seven cases of these amputations, collated by Dr. Fenwick,[2] one thousand five hundred and sixty-five died, *i.e.*, nearly one in three. These deaths after operations depend, in a large proportion of cases, on a combined febrile and inflammatory morbid state, generally, if not specifically, the same as Puerperal Fever, and which may as correctly be denominated "Surgical Fever" as the other is denominated "Puerperal Fever".

A strong analogy, if not an identity, between these two forms of disease, is indicated—1. By the anatomical conditions and constitutional peculiarities of those who are the subjects of them. 2. By the pathological nature of the attendant Fever. 3. By the morbid lesions respectively left by each disease. And 4. By the symptoms which accompany each affection.

1. ANALOGY IN THE ANATOMICAL CONDITIONS OF THE SUBJECTS OF PUERPERAL AND SURGICAL FEVER. In the surgical patient, we have a solution of continuity, on the exterior of the body, with numerous arteries and veins opening on the free surface of the wound. In the puerperal patient, we have a solution of continuity on the whole internal surface of the womb, made by the separation of the placenta, and the exfoliation of the decidua or mucous membrane of the uterus; this wound has, opening on its free surface, the mouths of numerous arteries and veins; and it is repaired by the exudation of serum, lymph, and pus, (lochial discharge), and by the formation of a new layer of mucous membrane. Both classes of patients are liable to present the symptoms of shock or collapse, and a subsequent limited febrile reaction,—the traumatic fever of the surgeon, the so-called milk fever of the obstetrician. In both instances, the secretions of the wounds may morbidly alter; or they may become the seat of an excess of inflammation or ulceration; or of phlebitic suppuration and its consequences. In both cases, air may enter by the open mouths of the veins; both may, though very rarely, be followed by delirium, tetanus, and other nervous complications; and in like manner, but much more frequently, they are apt to be followed by that form of combined febrile and inflammatory action which we term Surgical Fever in the surgical patient, and Puerperal Fever in the puerperal patient.

2. ANALOGY IN THE PATHOLOGICAL NATURE OF PUERPERAL AND SURGICAL FEVER. Two opinions were formerly held as to the nature of Puerperal Fever: 1. That it was an idiopathic or putrid fever, *sui generis*; 2. That the disease was essentially a local inflammation, of which the fever was merely a consequence, and that the appropriate treatment was by venesection and active antiphlogistics. The first of the doctrines was generally abandoned

---

[2] Edinburgh Monthly Journal, 1847, p. 238.

as pathological anatomy advanced, because local inflammatory lesions, discovered after death in the uterus, peritoneum, and chest, were too frequent and too decided to be explained by the doctrine of a previously existing fever alone. Again, the idea of the disease being essentially a local inflammation, has been disproved, from its being found, 1. That there is no general uniform relation between the intensity of the local inflammatory lesions and the attendant fever; 2. That the supposed cause, simple peritonitis or metritis, may exist without exciting the symptoms of Puerperal Fever; and 3. That true and fatal Puerperal Fever may occur, without leaving on the dead body any traces of the local inflammation which had been considered the origin of the disease. Thus, whatever be the site of the local inflammation to which Puerperal Fever has been attributed, cases of genuine and fatal Puerperal Fever have been observed, in which each of these supposed causes has been absent.

Some authors, maintaining the disease to be a symptomatic fever, hold that the inflammation on which it depends may be seated in different parts in different cases, and in different epidemics, originating in one case, in metritis, in another, in peritonitis, and so on.[1] But occasionally, though very rarely, no inflammatory lesions whatever are found.[2] Hence most of our best pathologists have rejected the idea of Puerperal Fever being either a fever *sui generis*, or symptomatic of a local inflammation, and have been inclined more and more to ascribe the disease to a *toxæmia*, or morbid state of the blood. The injection of pus, and other morbid matters, into the blood of the lower animals, produces symptoms during life, and lesions found on the dead body, very analogous to those of Puerperal Fever. Similar effects are produced by the mixture of pus with the blood in the human subject, in cases of phlebitis, etc. Facilities for the access of pus to the circulation, after parturition, exist in the orifices of the utero-placental veins, in the inoculation of morbid and contagious matters upon the abraded surface of the vagina, and in the transmission, by continuity, of accidental inflammations from the lining membrane of the maternal passages, through the open orifices of the veins, along the lining membrane of these vessels. Under the view that Puerperal Fever is of toxæmic origin, we can more easily explain the relation of its two elements, viz., the febrile action, and the internal inflammation. For we see that the fever is not itself the cause of the attendant inflammations, nor these inflammations the cause of the fever: but that both the fever and the inflammations are the simultaneous effects of one common cause, namely, the vitiated condition of the general circulating fluid. The same doctrine enables us also to see how, in one epidemic, the febrile, and in another, the inflammatory element, may be more prominent.

These views of the pathology of Puerperal Fever are borne out by what we see in Surgical Fever and its inflammatory results, among the internal viscera of the body; for no pathologist has ventured to maintain, that the pleurisy or peritonitis, which we often see in the bodies of patients who have died of Surgical Fever, is the consequence of that fever; or that the fever itself is a consequence of these local inflammations. These local phenomena are no longer held to be explicable by the doctrine of sympathy or metastasis; and few now dissent from the idea that we are to look for their origin, and for the origin of the attendant fever, in some diseased condition of the blood. Whether this consists in the presence of some one or more of the elements of purulent matter alone; or whether other animal secretions may be its common or occasional cause, and its effects may not be regulated by differences in the diseased material which is present in the circulation, are questions which more advanced research may yet determine.

III. Analogy in the Internal Pathological Lesions left by Puerperal and Surgical Fever. Both are liable to leave upon the dead subject

[1] Tonnelle. Archiv. Gén. de Méd., vol. xxii, p. 350.

[2] Locock, in Library of Medicine, Art. "Puerperal Fever", vol. i, p. 351.

evidence of recent acute inflammation, generally characterized by an unusual tendency to the effusion of loose coagulable lymph and pus. Thus Dr. Chevers found, in 134 out of 153 cases fatal after surgical operations in Guy's Hospital, the immediate cause of death to have been acute inflammation in one or more of the internal organs; and, no doubt, in all of them, the usual symptoms of Surgical Fever were more or less perfectly marked during the last days of life. Similar results have been observed in cases of death from Puerperal Fever, as illustrated by the tables of Dugès and Tonnellé. The internal inflammation, in the same case, generally affects two or more different, sometimes very distant viscera, either simultaneously or in succession. The principal seats of inflammation are often far removed from that of the original lesion. Thus, pleurisy is very frequently the result both of a surgical operation and of Puerperal Fever, and pneumonia is especially frequent after surgical operations.[1] In obstetric cases, the uterus, uterine appendages, and peritoneum are, however, the most constant seat of the internal inflammation, just as all kinds of wounds of the pelvic and generative organs are particularly liable to be followed by peritonitis, when they give rise to Surgical Fever. In Midwifery cases, not only is the uterus, the seat of the original wound, liable to inflame, but the morbid action readily extends, by continuity of tissue, to its appendages and to the peritoneum. The pelvic viscera, moreover, have been the immediate seat of injury during parturition, and the inflammation is prone to attack any weak or injured part. Might we, in any case, regulate in any degree the principal site of the secondary inflammatory effusions in Puerperal or Surgical Fever, by lowering the vitality of a selected portion of the surface of the body?

IV. Analogy in the Symptoms of Puerperal and Surgical Fever. The type and severity both of Surgical and of Puerperal Fever are very variable. The varieties of the latter are described as the inflammatory, the bilious, the gastro-enteric, the nervous, etc. But when either disease is fully marked, the symptoms are sufficiently striking and similar: as rigors, a pulse varying in strength but always rapid, an altered hue of the surface, which is frequently darker, or almost icteric; the skin hot and dry, or bathed in perspiration, or these states alternating, without any material crisis in the febrile action: local pains, and functional derangements in the parts which are the seat of the internal inflammatory effusions, while the local symptoms of the local inflammations are often very masked and latent; anxiety and general prostration, adynamia; very frequently nausea and vomiting, occasionally diarrhœa; and latterly, laboured or hurried respiration; sometimes sudden swellings and effusions of the joints and subcutaneous tissue; and often at last rapid sinking, with or without delirium. There is no disease in which it is so difficult to assign pathognomonic phenomena as in Puerperal or in Surgical Fever. But whoever has seen much of the disease in one class of patients, has no difficulty in identifying it in the other class.

The discovery of any measure for the prevention or cure of Surgical and Puerperal Fever would save numerous lives, and form a most important era in the march of professional discovery. We already know various conditions capable both of increasing and decreasing the intensity of this affection. The disease is more common and severe in towns than in the country,[1] in hospitals than in private practice, in crowded wards than in those where the patients are few and the supply of fresh air ample. In some epidemic states, in some localities, and in some states of the economy, it is much more fre-

[1] Erichsen, Professor, in Med. Chir. Trans., vol. xxvi. Dupuytren, Révue Médicale, 1826, vol. iv, p. 418. Addison, Dr. Thomas, in Guy's Hospital Reports, 1843, p. 83.

[2] Out of a town population of about 1,800,000, 3195 died in child-bed in four years; and in about the same amount of rural population, there died only 1806 mothers. Mr. Farr, in Registrar-General's Fifth Report, p. 400.

quent than in others. Patients suffering under internal organic diseases, particularly of the abdominal viscera, and under certain functional derangements of the kidney, and perhaps of other organs, are specially liable to be attacked with this consecutive fever and inflammation. In addition to the common antiphlogistic remedies, special prophylactic measures have been proposed when Puerperal Fever is epidemic, as large and repeated doses of quinine, chlorate of potash, etc., before or immediately after delivery. This is a line of inquiry deserving further careful investigation. Some surgeons subject their patients to previous regiminal and medicinal preparations, but the exact power and propriety of these and other measures are not precisely ascertained. With regard to Puerperal Fever, few practitioners in this country have any doubt of the propriety and efficacy of those measures, which are calculated to prevent the medical practitioner or the nurse being the unhappy medium of carrying the contagion of the disease from one puerperal patient to another. There is amply sufficient proof that puerperal women may be inoculated with a *materies morbi* capable of exciting Puerperal Fever; that this *materies morbi* may be introduced into the dilated and abraded lining membrane of the maternal passages during delivery, by the fingers of the attendants; that the *materies morbi* most capable of being thus inoculated, and of generating the disease, seems to be the inflammatory products effused upon the serous or mucous surfaces of females who are suffering under Puerperal Fever, or who have died of it; and lastly, that other inflammatory effusions, when inoculated into the puerperal female, appear to have sometimes the same effect, such as the effusion into tissues, which are the seat of an asthenic, erysipelatous, or gangrenous type of inflammation. Every available caution should be taken against propagating the disease in this manner. The omission of these precautions, it is sincerely believed, has proved the cause of many deaths in child-bed, and continues still to do so, particularly on the continent of Europe. In the large hospital of Vienna, out of 21,120 women delivered from 1840 to 1846, 2260 died, or about 1 in every 10 mothers delivered, perished chiefly from Puerperal Fever. Latterly, this mortality has diminished so far, that in 1848, not above 1 in 74 died. This great change was effected by the adoption of means to prevent the contagion being transferred by the medical attendants and students, the mortality diminishing immensely and immediately from the time (May 1847), that the assistant-physician, Dr Semmelweis, prevented students from touching parts at the autopsies, and directed all of them to wash their hands in a solution of chlorine before and after every vaginal examination.[1] Was not the want of a due knowledge of the communicability of Puerperal Fever the cause immediately leading to these numerous maternal deaths? Were these mothers not sacrificed merely to medical prejudice, in the form of a total disbelief, on the part of our own continental brethren, in the contagious communicability of Puerperal Fever? And lastly, if Puerperal Fever be occasionally produced by inoculation, may not Surgical Fever be sometimes communicated in the same way?

The Dublin correspondent of the *Medical Times* for December 14th, makes the following remarks, in referring to Dr. Simpson's memoir:

The idea of the identity of Puerperal and Surgical Fever has been long held in Dublin, and is by no means new. The view was well put forward not long since, by Dr. Henry Kennedy, at the Dublin Obstetrical Society. The uterus Kennedy looked on, after delivery, as a large open wound; amputation, so to speak, of the mass of the placenta having taken place. At particular seasons, Puerperal Fever is more fatal. There is a large group of diseases, he thinks, to which it belongs, typhus, the exanthemata, diffuse

[1] Wieger, in Rev. Medico-Chir., vol. vi, p. 136. Routh, in Med. Chir. Trans., vol. xxxii, p. 27.

phlegmon, erysipelas, dissection wounds, etc. Kennedy, with Fergusson, is of opinion that the disease is rendered fatal by the formation of a poison in the system of the patient herself. He thinks the disease *then* becomes contagious, and may be carried by a third party, as a student, or midwife. In his own practice, a woman in perfect health was confined in a room adjoining one where there was a bad case of typhus. She suddenly got Puerperal Fever, and died. Kennedy has also seen the dark mulbery *vibices*, or spots of typhus, in Puerperal Fever. The fever is the chief thing to contend against in the treatment, not the peritonitis, he says, which is only secondary: he is accordingly against the system of bleeding; and mercury, where the system is deeply poisoned, he thinks quite as inadmissible.]

SUDDEN DEATH SEVEN HOURS AFTER DELIVERY: AIR FOUND IN THE HEART.

Professor Samuel Berry, of Queen's College, Birmingham, relates, in the *Provincial Medical and Surgical Journal* for November 27th, 1850, the case of a woman who died suddenly after delivery, and in whom, on post-mortem examination, air was found in the heart. There is by no means sufficient proof that the entrance of air into the veins was the cause of death; as may be inferred from a comparison of the case with the views advanced by Dr. Cormack, in this Journal, for October 1850, and with the experiments and observations of Amussat, Wattmann, Erichsen, and others. We give the case, however, as it is possessed of some interest.

Case. A woman, primipara, aged 22, had a favourable delivery; the placenta was expelled, with little loss of blood, at 20 minutes past 7 p.m. She appeared to be going on well until 1 a.m. the following morning, when she became affected with difficulty of breathing and faintness, and expired before the arrival of her medical attendant, Mr. Dyer, about an hour afterwards. On a *post-mortem* examination, performed the next day, the lungs were found congested, and there was air in the heart, which was of the size of a male heart, and apparently distended. Upon making an incision into it, a gush of air escaped, and the organ became flaccid: no blood was found in its cavities. The uterus was found empty, and the vessels, where the placenta had been attached, were patulous. The vagina contained, at its upper part, a moderately-sized clot of blood. Mr. Berry gives the following explanation of the case: The uterus, after the removal of the placenta, contained a clot of blood, which, by the contraction of the uterus, was forced into the vagina; when the uterus was relaxed, air was drawn into the cavity, the clot on the vagina prevented the air from passing out of the uterus, and the mouths of the uterine veins being patulous, it was forced into them, and then passed into the general venous circulation. The entrance of the air was gradual, he believes, and therefore occupied some time before it reached the heart in sufficient quantity to give rise to those symptoms of obstructed respiration which soon terminated in death.

KEY-TSI-SING, A JAPANESE REMEDY FOR STERILITY AND SUPPRESSED CATAMENIA.

In our number for November last, p. 1083, we noticed a Japanese remedy, introduced (through the *Lancet*) to the notice of British practitioners by Dr. E. Williams. We find a second eulogy of the medicine by Dr. Williams in the *Medical Times* of December 21st, supported by the details of a case of suppressed catamenia, in the practice of Dr. White of the Winchester County Hospital. As Dr. E. Williams states, that forty-seven practitioners have testified to him in favour of the beneficial effects of the drug in suppressed catamenia, we think the present publication of a single case ill-advised. When the results of the trials of the forty-seven practitioners referred to are laid *in extenso* before the profession, we will state the results to our readers.

THE HOSPITALS OF LONDON.

BY DR. CORMACK AND DR. SEMPLE, ASSISTED BY NUMEROUS REPORTERS.

INTRODUCTORY REMARKS.

Under this head we propose, from time to time, to offer a series of facts and observations regarding the London Hospitals. Our object will be, not so much to give details of individual cases (although these, if interesting, will not be excluded), as to furnish an outline of the statistics of the Institutions, of the practice of their different physicians and surgeons, and of the system of instruction pursued by each of them.

The paramount importance of clinical instruction has always been insisted upon in this journal; and we are happy to observe that the Court of Examiners in the Society of Apothecaries have, in their last curriculum, (published in the beginning of 1850,) made an attempt to place this branch of medical tuition on its proper footing; and no one who is acquainted with the excellencies and defects of our present system of medical instruction, can doubt that the Court of Examiners have exercised a sound judgment in this particular. Our only regret is, that the other medical corporations, especially the University of London and the Royal College of Surgeons of England, have not yet thought it necessary to follow so good an example.

With the view of aiding, as much as possible, the efforts of those who are endeavouring to promote a better system of clinical instruction, we propose to state, as far as our information extends, the various methods pursued of the London Schools of Medicine. On the present occasion, we present to our readers some particulars connected with the mode of clinical teaching adopted at Guy's and at University College Hospitals: which we have no hesitation in stating are both admirably regulated Medical Schools. We also give a short notice of the North London Eye Infirmary.

We give these Hospitals priority only from adventitious circumstances. It is no part of our plan to advocate the interests of any particular Schools, or any particular set of Teachers; we are anxious to do justice to all; and, as far as lies in our power, to make the stores of medical knowledge contained in our great hospitals, available to the medical community. Deeply sensible of the liberality which characterises the Hospital physicians and surgeons of London, we acknowledge with gratitude the zeal which they have evinced in placing within our power the means of communicating a vast mass of useful information: and it is our earnest desire, in return for the confidence reposed in us, to make the department devoted to the Hospitals of London one of the most useful features in this Journal.

We are by no means insensible of the valuable services rendered to Clinical Medicine by our weekly contemporaries; and our readers will perceive that it is no part of our plan to supersede their truly excellent reports. To the *Lancet*, special praise is due for having commenced effectively these valuable communications.

GUY'S HOSPITAL.

Guy's Hospital in the Borough of Southwark was founded at the sole cost of Thomas Guy in the year 1727. The hospital school, which was at one time connected with that of St. Thomas's Hospital, has now been separated from it for many years, and is carried on by a distinct and complete staff of lecturers. The number of beds amounts at present to 580, a considerable increase on the number originally determined upon by Guy. This extension

of the hospital was the result of a munificent bequest by the late Mr. Hunt, who left a sum of £200,000, to be devoted to the purposes of the institution.

The large number of patients constantly in the hospital affords great opportunities and advantages, for the instruction of pupils in the practice of medicine, surgery, and midwifery. The arrangements for carrying out this object are as follows. The general service of the wards is conducted on the ordinary plan, each physician being attended by four clinical clerks, (students of the second or third year) who report the cases coming under treatment, and each surgeon being followed by four dressers, and four surgical reporters for the like purpose. During the six winter months of the year, from October to the end of March, the medical and surgical *clinical wards* are open; forty beds are devoted to this service for the physicians, containing twenty-two male and eighteen female patients. The six months are equally divided, each physician taking the wards for two months, during which time he lectures once a week on the cases admitted. Clerks for the clinical wards are selected from among the most assiduous pupils of the third year, and the same rule is adhered to in the selection of dressers. The surgical clinical cases are distributed, and selected from cases in the surgical wards; the clinical surgeon for the time being having the liberty of selecting such as he may choose from all the cases admitted. For these cases there are special reporters, and the surgeon who takes the clinical duty for two months, lectures once a week during that period on the cases requiring notice. In this way it will be observed, that while arrangement is made for reporting all the cases contained in the hospital, the clinical wards and other selected cases supply matter for clinical lectures during the winter session. One great advantage of these arrangements, consists in the means they afford of obtaining a knowledge of the capabilities of students as reporters, while labouring in the general wards, so that the care of the selected cases devolves on those who are not only the best fitted to report, but also to have the care of patients suffering from the severer forms of disease. The Eye Wards, male and female, containing thirty beds, under the care of the ophthalmic surgeon, are open all the year round, clinical lectures being delivered during the summer.

Clinical instruction is also given by the physician-accoucheurs—Dr. Lever and Dr. Oldham—who have twenty beds in the hospital for the reception of women suffering from diseases of the uterus. Two clinical clerks, selected for the most part from students of the third year, attend upon these cases and also assist the physician-accoucheur with the out-patients of this department, which average 160 each week.

For the purpose of teaching practical midwifery, a house has been appointed in the hospital for the residence of three students, who take office under the following conditions. There is a senior, second, and third; the youngest is in attendance for *a fortnight*, during which time he attends all the ordinary cases which occur, amounting to from twenty-five to thirty cases. Having performed this duty satisfactorily, he is eligible for the appointment as second, who has allotted to him such cases as from circumstances may be known to present abnormal conditions: this duty he performs for a month. If his attendance has been satisfactory, he is chosen to the office of senior, whose privilege it is, under the sanction and in the presence of one of the physicians, to perform the operations of turning, applying the forceps, etc., or if capable, he is permitted to undertake, with their sanction and in their presence, any required operation. He resides for two months, and is responsible for the regularity of the others, and assists them in cases requiring particular attention. The cases are attended at their own homes, books being kept in which the names of women are entered, with the time at which they expect to be confined, and such other particulars as may be thought necessary. The annual number attended is about 1400.

During the time the clinical wards are closed, a clinical lecture is given once a week by one of the three assistant-physicians, Dr. Hughes, Dr. G. O.

Rees, and Dr. Golding Bird. These lectures include the subject of Diseases of Children, a children's ward containing beds being open all the year round, under the care of one of the assistant-physicians.

Clinical lectures are thus delivered during the whole year on Medicine, Surgery, Ophthalmic Surgery, and the Diseases of Women and Children. It may be stated, that in order to secure the undivided attention of the physician for the clinical wards in the winter session, each physician, on taking that duty for two months as before-mentioned, deputes his assistant-physician to undertake the service of the general wards.

The general management of this plan of instruction is under the superintendence of a clinical censor, who keeps lists of the clerks to each medical and surgical officer, and a register of those who, from standing and capability, are fitted for the offices of reporters or dressers. Further particulars regarding Guy's Hospital (to secure accuracy), we defer to a future occasion.

UNIVERSITY COLLEGE HOSPITAL.

University College has taken the initiative in clinical teaching, as in many other branches of education. Eleven years ago, for the first time in any English medical school, distinct professors were appointed, whose special duties were to superintend the practical training of students at the bed-side of the sick. In common with all the British schools, clinical instruction had been previously given by the several physicians and surgeons of the hospital; but by the institution of distinct professorships, the amount and efficiency of this teaching was extended. The clinical duties of the medical officers were not abolished, but the old system was developed and perfected.

Dr. John Taylor (now of Huddersfield) was the first Professor of Clinical Medicine, and Mr. Liston the first Professor of Clinical Surgery in University College. Dr. Walshe and Dr. Parkes have been, successively, the successors to Dr. Taylor; and Mr. Quain now holds the chair once filled by the greatest operator of modern times.

We have already said, that the clinical duties of the physicians and surgeons were not superseded by the creation of special clinical professors. Thus, for example, Dr. Walshe, Dr. Garrod, and Dr. Murphy, the three other physicians to the hospital, are still termed in the Prospectus, *Clinical* Professors, and are expected to give instruction at the bed-side; so also Mr. Erichsen is Clinical Professor of Surgery. But these professors are not expected to bestow the same amount of labour on their pupils as the special clinical professors. On Dr. Parkes devolve the duties of practically teaching the stethoscope, the art of percussion, the method of examining the urine, etc., in addition to pointing out the general phenomena of each case; and Mr. Quain's duties embrace corresponding practical instruction in surgery. In addition to the officers above mentioned, the Council have recently created a chair of Ophthalmic Surgery, and this is now occupied by Mr. Wharton Jones. Courses of instruction in Dental Surgery have been for some years given by Mr. Durancé George.

The Hospital contains 120 beds, of which about one-third are devoted to surgical cases. Into the medical side, the worst cases only are admitted, out of the great number always applying for admission; so that the examples of disease presented are of extraordinary severity as compared with the average of the cases in the large hospitals.

Confining ourselves on this occasion to the medical side, we find that the usual mode of examining patients, and dictating in a loud voice to clinical clerks,[1] has been adopted in this hospital ever since it was opened. This plan, which originated in the Edinburgh School, can never be superseded, and of itself is of great use, as placing before every student phenomena with whose

[1] The Clinical Clerks are students who have distinguished themselves for intelligence, industry, and good character.

characteristics he may subsequently make himself acquainted by personal investigation of the patient. In University College Hospital, the cases are taken with extreme minuteness and care.

The following is the plan which Dr. Parkes, the present clinical professor, has used since his appointment :[1]

A. GENERAL PREVIOUS HISTORY.

1. *Name*—age—place of birth—place of usual residence—how long in London—general health of parents, brothers, sisters, and other relations—mode of death of ditto.
2. *Conformation and appearance when in state of health*—height—weight—make of body (tall—slight—short—square, etc.)—colour of hair and eyes—temperament—habitual state of mind—cheerful—melancholy, etc.
3. *Trade*—sedentary or active—in or out of doors—how many work-hours per diem.
4. *General mode of life*—lived well or badly—amount of meat and fresh vegetables—temperate or not—amount of liquor and of what kind—tobacco—clothing—personal cleanness as to baths, etc.—exposure to weather—how much sleep—number of persons in same room—married or single—how many children—place of abode—humid, dry, well, or badly drained, etc.
5. *Previous health in general terms*—good—bad, etc.

If a female—catamenia, at what age appeared first—second appearance—when quite regular—regular or not since—scanty or profuse—how many children or abortions—labours easy or the reverse—any flooding—suckled her own children—when catamenia ceased.

6. *Previous Diseases*—(The patient should be first asked to enumerate them, afterwards special inquiry should be made as to the following, viz.)

Small-pox—cow-pox—pertussis—scarlatina—measles—rheumatism, acute or chronic—rheumatic or neuralgic pains—palpitation of the heart—winter cough—hæmoptysis—epistaxis—hæmatemesis—indigestion—piles—syphilis, primary or secondary—gonorrhœa.

Accidents, as blows—strains—heavy falls.

B. SPECIAL PREVIOUS HISTORY.

(*i. e.* of the disease for which advice is sought).

Exact date of commencement. Then the symptoms should be taken down as nearly as possible in the patient's own words.

C. PRESENT STATE.

(*a.*) The patient should be called upon to state what he feels to be the matter with him. Answers should be taken down in his own words. No leading questions should be asked.

(*b.*) The patient should then be questioned concerning the following subjective symptoms, supposing that they have not been mentioned :—Pain—aching and soreness—feelings of uneasiness or prostration—flushes—coldness or shivering—tingling or burning—alterations of vision—hearing—touch—taste or smell—numbness of extremities—altered or impaired cutaneous sensibility—dyspnœa—desire to cough or cough—palpitation—choking—dysphagia—degree of appetite—thirst—nausea—desire to micturate—griping—tenesmus, etc.

---

[1] Dr. Parkes has informed us, in answer to our application to be permitted to publish his plan, that he has been obliged to sacrifice exact scientific arrangement, in order to make the examination as direct and short as possible, for the convenience of the physician as well as of the patient. But it is quite easy afterwards to bring together all symptoms connected with any organ, as for example, the lungs, if an exact arrangement be required.

(*c.*) Objective symptoms (including any subjective symptoms which it is inadvisable to sever from the objective symptoms).

In noting these symptoms, it is advisable, in fevers and general constitutional diseases, to go regularly through the following list; but in other cases the examination may be commenced with that part of the body to which the previous examination has seemed to point as the seat of the disease; for example, great palpitation, dyspnœa, and pain in the cardiac region, should be followed by examination of the heart; cough and hæmoptysis, by that of the lungs, etc.

1. General Objective Symptoms, including a short description of the attitude, manner, aspect of the patient—emaciation—muscular strength—paralysis—twitches—convulsions, etc. Also at this time, before the patient is stirred, the pulse at the wrist and the respirations should be counted.
2. Surface.
   (*a.*) Colour of skin.
   (*b.*) Spots—sudamina or eruption of any kind.
   (*c.*) Dry or moist—if moist, perspiration acid or alkaline—smell.
   (*d.*) Temperature of skin (in axilla and groin).
   (*e.*) Œdema—flaccidity—rigidity of limbs.
   (*f.*) Superficial veins.
   (*g.*) Conjunctivæ—irides—cheeks—expression.
   (*h.*) Colour of lips and inside of mouth, including tonsils, tongue and palate; temperature; quantity and reaction of saliva.
   (*i.*) Joints.
   (*k.*) Nails.
3. Head—form of head—circumference—breadth—intellect—hearing.
4. Larynx—front of neck generally, pulsation in neck, venous or arterial, etc.; voice—tracheal rhonchus, etc.
5. Examination of front of Chest and Abdomen—(Patient recumbent).
6. Chest.
   (*a.*) General shape, etc.—degree of prominence of clavicles—post and infra-clav. spaces—post-sternal space—any general or partial bulging or retraction, etc.—width of intercostal spaces.

Lungs.

   (*a.*) Expansion as ascertained by the eye and hand—intercostal spaces marked or not in full inspiration—full expiration—relative duration of inspiration and expiration.
   (*b.*) Expansion as ascertained by the chest-measurer.
   (*c.*) Measurement of chest—circumference immediately below axillæ—right and left—full expiration—full inspiration.

At point of ensiform cartilage—full expiration—full inspiration.

Sterno-clav. to nipples—middle line to nipples.

   (*d.*) Vocal fremitus—in infra-clav.—mammary and lateral regions—friction or rhonchal fremitus—purring tremor or thrill of any kind.
   (*e.*) Percussion—post-clav.—clav.—infra-clav.—first on one, then on the other side—post-sternal—sternal throughout—mammary—infra-mammary—axillary—infra-axillary.
   (*f.*) Respiration—in same regions above—distinguishing between inspiration and expiration, in easy, deep, and tussive respiration.
   (*g.*) Voice in same parts.

Heart.

   (*a.*) Apex—place where—kind and strength of impulse—whether any pulsation elsewhere—purring tremor, undulation, etc.
   (*b.*) Percussion note of 1st, 2nd, 3rd, 4th, and 5th left cartilages and 4 first interspaces, as compared with right side—percussion for inner or right line of cardiac dulness; then for the outer or left line—shape of dulness.
   (*c.*) *Sounds*—2nd right cartilage—2nd left—midsternum—apex—point

of ensiform cartilage—outside left nipple—top of sternum—in neck—is there any friction?

(In cases of diseased lungs and heart, mark sounds of heart all over chest, front and back.)

The first and second sounds must be listened to separately.

7. Abdomen.

(*a.*) Shape—circumference round navel, if there be any abdominal disease—resistance of walls—tenderness.

(*b.*) *Liver*—upper and lower edge in full expiration and inspiration—height of liver (also length of trunk from upper edge of sternum to pubis)[1]—can edge be felt?—is it rough—smooth—round—sharp, etc.?

(*c.*) *Spleen*—size by percussion—auscultation for splenic murmurs.

(*d.*) Percussion of abdomen generally, marking out if any dull parts.

(*e.*) Auscultation if necessary—temperature if abdominal disease present.

Special examination for tumours—fluctuation.

8. Examination of the Back.

(Patient sitting up with the arms crossed.)

General Inspection—supra-spin. fossæ—movements of ribs by eye and chest-measurer—general or partial bulging—dorsal arch—curvature of spine—tenderness of spine.

Vocal fremitus.

Percussion—supra-spinous fossæ—infra-spinous—interscapular angles of scapulæ—bases—mark out lower edge of lungs—auscultation for respiration and voice in same regions.

Examine loins and mark out kidneys by percussion—grasp kidneys.

9. Excretions.

Expectoration—quantity in twenty-four hours—colour—consistence—form—surrounded with thin fluid or not—aërated or not—microscopic characters—reaction.

Urine—quantity in twenty-four hours—specific gravity—reaction—appearance and colour—does it contain albumen—sugar—bile?—quantitative analysis.

Sediment—character to naked eye—microscopic examination—chemical tests.

Fœces—number of stools—quantity—colour—reaction—microscopic characters.

10. Blood—microscopical and chemical examination—physical appearances—of clot and serum—reaction, etc.

In certain cases, examination of uterus by touch and speculum—of anus and urethra.

In cases in which it is not possible to go fully into the examination, after a short general previous history, the special previous history should be followed by an examination into the part to which the symptoms point as the seat of the disease; then in addition to the usual subjective and objective symptoms, the following points may be more or less closely examined:—

1. The apices of the lung in front and behind.
2. The sounds of the heart.
3. The condition of the abdomen as to fulness, tenderness, etc.
4. The state of the urine and fæces.

Dr. Walshe's method differs from this, in the minuteness with which the circumstances connected with the previous health and condition of the patient are recorded.

The clerks not only take down the cases to the dictation of the physician, but on them devolves especially the examination of the urine. In every case, the quantity of urine passed in twenty-four hours is recorded; the

[1] This point is merely inserted to aid an inquiry in which Dr. Parkes is at present engaged.

urine is tested for albumen, sugar, and bile, and the microscopic characters of the sediment (if any) are noted.[1]

The minute accuracy with which the cases have been taken in University College Hospital for a number of years by the successive physicians, has led to the accumulation of an immense number of complete histories of disease in the hospital registers. But the immediate effect on the mind of the student of this careful investigation, is still more important. He receives at once the lesson, that those who have from their vast opportunities become most conversant with disease, yet deem the severest scrutiny essential before they pronounce on the nature of the affection they have before them. He is at once taught, that an accurate diagnosis is the great aim of his teachers, and that the successful attainment of this object requires on their part no slight labour and consideration. And in the extraordinary success with which the exact condition of organs can be often determined, the student will learn that this labour and consideration may meet with ample reward, as he may, on the other hand, perceive, in the errors which must occasionally occur, that there is yet room and verge enough for amplification and correction in the mode of investigating disease. Clinical lectures are delivered twice a week by the special Professor of Clinical Medicine, and once a fortnight by each of the other physicians. In these lectures, each case is reviewed after its termination; or, as we understand is Dr. Parkes's present plan, the cases while still in hospital, particularly those likely to have a fatal termination, are minutely considered, so that the students may have frequent opportunities of comparing symptoms and *post-mortem* lesions, and of observing how far the grounds for the diagnosis have been found valid.

In addition to clinical lectures, the physicians are in the habit of lecturing upon cases at the bed-side, and the pupils are also called upon, as far as the time will permit, to examine the patients for themselves. But, in the space of time which can be devoted to the visit, it has been found impossible to give the student sufficient instruction as to the manner of conducting this examination. It was for the purpose of supplying this deficiency, that the special Professorship of Clinical Medicine was founded.

The increased accuracy of diagnosis which is becoming so conspicuous a feature in the profession, is owing to several causes, but most particularly to the cultivation of various kinds of physical examination. In cases in which the ancient physician, or even the physician of sixty years since, depended for his diagnosis chiefly on the symptoms derived from the sensations of the patient, or on the few objective symptoms which were appreciable by him (as, for example, the state of the skin, the tongue, the expectoration, the pulse, or the physical appearance of the urine) the physician of the present day brings to bear a host of appliances for a closer investigation. He measures, he percusses, he listens, he weighs, he has recourse, in fact, to a number of means by which he ascertains the state of the patient, without a word being uttered by either party. Within the last few years, fresh modes have become available; and the microscope and the test-tube have come into daily use in the chambers of the sick. So important and so accurate is the information which the combined use of these methods gives, that it is not too much to assert, that he who can avail himself of these aids to physical diagnosis, need not fear to affirm the diagnosis after a proper investigation, in almost all general diseases, and in the infinite majority of local chest and abdominal complaints, and in many head affections which come before him.

The acquirement of these several methods is a study, which we have yet

[1] We have not alluded to the office of Physician's Assistant, which in University College is filled by old students, who are elected every six months by *concours*. It is a post of great importance, and very instructive to those who hold it.

to see take its place by the side of those which are deemed most essential to the education of a physician. What his dissections are to the anatomist, or his balance and test to the chemist, or his measurements and calculations to the astronomer, so is his stethoscope, his measurer, his test tube, his pleximeter, his speculum, or his microscope[1] to the practising physician. They are his tools, his implements of labour ; and unless he learn to use them, he would, with all the theoretical knowledge in the world, be like, when brought to the bedside of the sick, an anatomist who had never touched a scalpel, or an astronomer who had only read of telescopes. And it may be safely asserted, that the student who can use well these modern appliances, will be able, after he has seen only a small number of cases of disease, to make a more accurate diagnosis, than the old routine practitioner, whose so-called "experience" consists only in the inaccurate observation of multitudes of patients whose diseases he never fully comprehends.

Each physician in University College Hospital is, of course, a clinical professor ; but those who are not the special professors, necessarily and most usefully tend, in their instructions, towards that point where lie their favourite studies. Thus, Dr. Walshe (in addition to the usual general instruction concerning the course of nature and treatment of diseases) is most full and explicit in all information relating to physical examination. Dr. Garrod, on the other hand, is rather led, by the prevalent nature of his studies, to consider more closely the chemistry of the fluids, and the action of medicines, etc. Dr. Murphy, again, gives practical instruction in the use of the speculum, and other means which are used in the examination of the female organs.

The duties of a clinical professor, however, embrace the whole range ; and he should be at once competent to use the stethoscope and the speculum, to analyze blood or urine, and to distinguish, under the microscope, the histological elements which most especially aid in diagnosis.

In order to teach the principles of physical diagnosis, the special Professor of Clinical Medicine gives, to small classes, practical instruction at the bedside, on the position and movements of organs, on the stethoscope, the art of percussion, measurement, etc. Each of these courses which have been regularly given since the foundation of the chair, occupy about six or eight weeks, a space of time in which the principal facts can be mentioned and illustrated ; so that, with the necessary labour which every student must bestow upon his own improvement, a competent working knowledge may be acquired. The applications of chemistry and microscopy to diagnosis, are brought forward as occasion may arise.

The *post-mortem* examinations are conducted by the physicians, who dictate aloud to the clerks the morbid alterations. This is, we believe, a better plan for the instruction of students, than leaving the *post-mortem* examinations to a special officer, who does not necessarily see the patients during life.

In order to encourage students to examine patients for themselves, and to commence the necessary training of those powers of observation which are to be so largely exercised in after life, gold and silver medals are awarded, every winter and summer term, to the authors of the best series of cases.

Such are, we believe, the means of instruction at University College Hospital. Altogether, the system pursued is a good one; and it will most probably be rendered still more efficient, as the officers of the hospital confess that there exist deficiencies in their method, and are constantly endeavouring to remedy them.

---

[1] It is evident, that as the applications of chemistry and the microscope to medicine develop themselves, the special assistance which these methods give to diagnosis, will become a distinct branch of tuition, that is to say, distinct from the general subject of the chemical and microscopic histories of disease. At present, however, the subject is too little advanced to permit this to be done.

NORTH LONDON EYE INFIRMARY.

This charity was established eight years ago. In the annual report for 1850, it is stated that during 1849, 1214 patients were treated: of this number 913 are mentioned as cured, 111 as relieved, 27 as incurable, and 163 as under treatment.

The following is a summary of the 161 OPERATIONS:

Cataract—Extraction, 11—Solution, 19—Depression, 2 ...	32
Tumours	41
Obstructed Lachrymal Duct	8
Entropium and Ectropium	5
Artificial Pupil	4
Minor Operations	71
	161

The affairs of this Institution are regulated by a committee annually chosen from the subscribers. Mr. Dalrymple is consulting surgeon, and the attending surgeons are Mr. White Cooper, Mr. G. Pollock, Mr. Pyle, and Mr. H. B. Norman. There is a surgeon daily in attendance from 10 to 11 A.M., Sundays excepted. Patients suffering from severe diseases, or requiring operation, are admitted into the house at the discretion of the surgeons: and in very urgent cases, the patients are allowed at all times to apply at their private residences.

The general character of the treatment pursued at the North London Eye Infirmary, is that which was so efficiently practised by the late Mr. Tyrrell, at Moorfields. Careful attention is paid to the general health, and especially to the removal of the causes of disease; depletion, by the abstraction of blood, is very little practised, and violent escharotic drops and ointment are quite proscribed, having been found not only unnecessary, but pernicious. Observations have recently been made to some extent, on the utility of the *neutral acetate of lead in granular lids:* although undoubtedly of service, it is not found to work the wonders which some foreign writers have ascribed to it, but it is regarded, at the North London Eye Infirmary, as a very useful auxiliary to other treatment. Mr. White Cooper has been trying the newly introduced medicine, *sumbul*, and is well satisfied with it. He says that it is of decided service in cases of debility as a tonic and restorative. In combination with colchicum, he recently found the etherial tincture of sumbul, of essential service, in the case of a patient whose constitution had been greatly broken by a dissipated life, and seven mercurial salivations. Being severely attacked with arthritic sclero-iritis, the ordinary treatment failed to subdue the attack; but on a trial being made of the combination above mentioned, he rapidly recovered. The *hydrocyanic acid vapour*, which has lately been lauded as a remedy for cataract, in a Canadian work, is often used to remove corneal opacities, in which it is decidedly beneficial; but though tried, it has never been found to produce the slightest effect either upon cataract or amaurosis. *Cod-liver oil* is found to be extensively useful in strumous ophthalmia. Children recover rapidly under its use, with mild local treatment, and counter-irritation.

At the present time, catarrhal and rheumatic affections of the eye appear to be very rife, but yield readily to treatment. In rheumatic sclerotitis, bark and soda, with or without colchicum, is found extremely beneficial.

[*In future we propose to prefix to our first notice of each Hospital a complete list of its Medical and Surgical Staff.*]

REPORTS OF SOCIETIES.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

November 26, 1850.

Dr. Todd in the Chair.

Chorea attended by Softening of a portion of the Spinal Cord. By R. Nairne, M.D. The patient was a lad, aged 17, who had been, from the age of 12, the subject of occasional attacks of articular rheumatism, with endocarditis and other complications. He was seized with Chorea ; and was admitted into St. George's Hospital on the 27th of last June. He was somewhat relieved by the treatment for the first day or two ; he then became more restless, delirious, more feeble, and violently convulsed. Some hours before his death, the convulsive movements ceased, and he became comatose. On *post-mortem* examination, twelve hours after death, the veins and sinuses of the cranium and spine were found congested. About an inch of the entire thickness of the spinal cord, opposite the third and fourth dorsal vertebræ, was white, softened, and almost diffluent, the rest of the cord being in its natural state. The brain was firm, and injected with blood. The pericardium was adherent ; the mitral valve was fringed with small vegetations. The lungs were congested.

Dr. Nairne referred to four cases, in which softening of the spinal marrow had been found in conjunction with Chorea : but he did not think there was any reason for supposing that the latter was an effect of the former. He remarked that the fact of the existence of sensation, and the transmission of nervous impressions to the palsied muscles of the lower extremities, notwithstanding the softening of the cord, showed that we had yet much to learn respecting its functions.

December 10, 1850.

Dr. Addison, President, in the Chair.

Case Illustrating Difficulty of Diagnosis in Tumours of the Superior Maxilla. By Prescott G. Hewett, Esq. A young man, aged 25, was admitted into St. George's Hospital, in May 1848, under the care of Mr. Hewett, with a tumour in the situation of the Superior Maxilla, encroaching somewhat on the orbit, and extending into the pharynx : it had existed five or six years. The patient frequently had hæmorrhage from the nostril on the affected side. It was determined to remove the tumour, which was thought to arise from the antrum. During the operation, however, it was found that the tumour, which was fibrous, originated from the back of the nasal cavity, and compressed the antrum. It had entered the orbit through the sphenomaxillary fissure, and passed backwards into the sphenoidal sinuses. Chloroform was administered before the operation, and a very little during its performance. During the operation, syncope ensued, and the patient was laid down, and a stimulant given to him. When he had recovered, the operation was proceeded with ; but the syncope returning, the patient was carried to bed. The whole time occupied in the operation was twenty minutes. He recovered his consciousness, but remained in a state of collapse, and died about an hour after the operation. As there had been difficulty of breathing just before his death, the crico-thyroid membrane was divided, and artificial respiration performed, but without effect. When the membrane was divided, some frothy blood issued from the larynx. At the *post-mortem* examination, portions of the tumour were found adhering to the sphenoid bone. The

trachea and bronchi, down to their minutest ramifications, contained frothy blood, and there were spots of ecchymosis throughout the lungs, denoting that some of the blood had entered the air-cells. The author considered that the blood must have got into the lungs during the operation, and that the chloroform might have impaired the irritability of the glottis, so as to favour its admission. He would be deterred from employing that agent in future cases of this kind.

MEDICAL SOCIETY OF LONDON.

J. Risdon Bennett, M.D., President, in the Chair.

Artificial Oviduct for the Cure of Ovarian Disease. By Mr. I. B. Brown. Mr. Brown exhibited a preparation taken from the second patient referred to at p. 1189 of this Journal for December 1850. Perfect adhesions had been established between the multilocular cysts, and the abdominal parietes. The uterus was healthy, and the other ovary free from disease. He had lately been informed, that the operation had been several times performed in Paris with success; but that adhesion of the abdominal parietes was effected by pinning the cyst to the walls of the abdomen some days before opening it.

Case of Cauliflower Excrescence from the Os Uteri: with Remarks. By Dr. Cormack. [This paper will be published as an original article in this Journal.]

December 7, 1850.

J. Risdon Bennett, M.D., President, in the Chair.

Crowing Inspiration in Infants. By Mr. Cox. The causes were considered under the heads of *predisposing*, *exciting*, and *proximate*. Among the proximate causes, Mr. Cox considered irritation of the trifacial nerves as most frequent. He believed that cutaneous diseases, such as eczema, were often the source of morbid action. He then made some remarks on the disease, contending that it consists in spasm of the laryngeal constrictors; and stated some objections to Dr. Ley's theory of its depending on paralysis. He endeavoured to trace an analogy between crowing inspiration and epilepsy, arguing—1. That the symptoms were identical in type: 2. That persons who in infancy are affected with the one, frequently become subjects of the other in adult age: 3. Epileptic patients often suffer from a suffocative spasm of the larynx at the onset of a seizure. In the symptoms, it was interesting to observe how distant parts of the diastaltic nervous system were affected; producing tenesmus, strangury, and obstinate closure of the sphincters. The remedies recommended were, chloroform during the paroxysm, citrate of iron as a tonic during the intervals, lancing the gums, and hydrocyanic acid to subdue the irritable condition of the spinal cord, after all sources of irritation connected with the excitor nerves had been removed. The dose of the latter remedy was a quarter of a minim three times a day to a child three years old, increased, if necessary, to half a minim. The author then read reports of twelve cases, nine of which had recovered under the use of chloroform and hydrocyanic acid. In one of the three fatal cases, there was aneurism of the arch of the aorta; and in another, there was myelitis, from a fall on the spine two months previously.

December 14, 1850.

J. Risdon Bennett, M.D., President, in the Chair.

Excision of the Head of the Femur. By Mr. Haynes Walton. The conclusion at which Mr. Walton arrived from an examination of this subject, was that there were cases of hip-joint disease, where the disease was limited to the

head of the femur, the acetabulum being healthy, or no longer implicated (that is, having recovered if it had been diseased), the head of the bone dislocated and lying in a sinus or abscess cavity, the patient sinking from external suppuration, there being no internal disease, or other manifestation of external local injury, in which the removal of the head of the femur would save life. He considered the operation, when the head of the femur was dislocated and lying loose, much less severe than is commonly imagined.

December 21, 1850.

Francis Hird, Esq., Vice-President, in the Chair.

Acranial Fœtus. Mr. Borlase Childs exhibited a fœtus, in which the bones forming the vault of the cranium were deficient, and the place of the brain was occupied by a spongy vascular mass, apparently loosely connected with the spinal cord.

Functional Paralysis. A paper on this subject was communicated by Mr. Edwin Lee.

MISCELLANEOUS INTELLIGENCE.

Royal Society. The Anniversary Meeting of this Society was held on Saturday, November 30th. The President, the Earl of Rosse, delivered the usual address. The Copley medal was awarded to Professor Hansteen, of Denmark, for his researches in astronomy; the Romford medal to M. Arago, for his numerous discoveries and improvements in optical science. The Royal medals were awarded to Professor Graham, of University College, for his contribution to the Transactions of a paper on the Motion of Gases through Tubes; and to Mr. Brodie, son of Sir Benjamin Brodie, for his paper on the Chemical Constitution of Wax. The following officers, whose names constituted the House-List, were elected for the ensuing year. President. The Earl of Rosse, K.P., M.A. Treasurer. Lieut.-Col. E. Sabine, R.A. Secretaries. Samuel Hunter Christie, Esq., M.A.; Thomas Bell, Esq. Foreign Secretary. Captain W. H. Smyth, R.N. Other Members of the Council. John Joseph Bennett, Esq.; William Bowman, Esq.; Sir Benjamin Collins Brodie, Baronet; The Rev. Professor Challis, M.A.; Lieut.-Gen. Sir H. Douglas, Baronet, G.C.B.; Sir P. de Malpas Grey Egerton, Baronet; John Forbes, M.D.; Marshall Hall, M.D.; Gideon A. Mantell, Esq., LL.D.; Professor W. A. Miller, M.A.; Sir Roderick Impey Murchison, M.A.; Richard Phillips, Esq.; Rt. Hon. Sir Frederick Pollock, M.A.; George Rennie, Esq.; Edward Solly, Esq.; Lord Wrottesley.

The total receipts during the past year, exclusive of the balance, amounted to £3176 19*s.* 6*d.*, and the expenditure during the same period, exclusive of the sum of £600 invested in the funds, was £3000 5*s.* 7*d.* Under the head of Donation Fund, the Society has paid £250 during the past year, as follows: To Dr. Hofmann, for Chemical Investigations, £100; to Mr. Miller, for Meteorological Observations, £50; to Mr. Newport, for Physiological Investigations, £50; to Dr. Frankland, for Chemical Investigations, £50.

Veterinary Masses. Dr. Kreuzer, Professor at the Veterinary College, at Munich, has been peremptorily removed from his office, in consequence of his having in his lectures adverted to the superstitious practice, of which some recent instances had occurred, of the people calling in the Franciscans to read masses for their cattle during an epidemic.

Exhibition of 1851. Mr. Erasmus Wilson has been appointed Chairman of the sectional committee for the exhibition of surgical instruments at the forthcoming display of the industry of all nations.

Bengal Medical College. This institution, which has now been established fourteen years, continues to flourish vigorously. It was here that the superstitious prejudices of the Hindoos against the handling of dead bodies, were first overcome by the example of a native student; and we find that, during the last session, sixty-three students were in attendance on anatomy and physiology, and during that time had dissected two hundred and twenty bodies, and performed operations on ninety-one. In connexion with the College, a hospital has just been established for the relief of the sick poor of all classes and creeds in the city of Calcutta, and particularly for those affected with epidemic diseases; the money for building which, has been partly raised by public subscription, and the remainder by private native liberality. Dr. Goodeve, the Professor of Midwifery, has most generously placed in the hands of the Council of Education, the sum of 3600 rupees, in government securities, for the perpetual maintenance of a midwifery scholarship of 16 rupees a month, for the best student of the midwifery class; to be awarded only to matriculated students of the medical college, who are *bonâ fide* natives of India, of Hindoo or of Mahommedan parentage, as long as such young men can be found in any way qualified to perform the duties of the office.

University College. We regret to find that Professor Graham is in very bad health. Professor Sharpey is not to be transported to Edinburgh, as was lately rumoured.

Bloomsbury Dispensary. The following gentlemen are candidates for the appointment of Physician to this Dispensary (to which is attached, as also to the surgency, a salary of £100 a-year), Dr. Goodfellow, Dr. George Johnson, Dr. Steggall, and Dr. Pidduck.

Marylebone Dispensary. The Governors of this Institution, we are happy to learn, propose to resume the payment of their medical officers. That the medical officers of all charities are not remunerated, is to be regretted.

Hagyard *v.* Coates. On the 19th inst., in the County Court, Bridlington, Mr. Hagyard, surgeon of Hunmanby, brought an action against J. Coates for 15*s.*, for attendance in midwifery upon his wife. The defendant pleaded his inability to pay this amount. His Honour, Judge Raines, inquired the usual amount paid by the Board of Guardians in cases of midwifery; and was informed that 10*s.* 6*d.* constituted the sum paid for confinements, without regard to distance, which induced His Honour to give a verdict of 10*s.* 6*d.* for the plaintiff. Although the plaintiff, a most respectable man, swore that Coates was able to pay the amount at once, the Judge directed him to pay 2*s.* a month. Thus the Profession will perceive that County Court law professes to regulate the charges of medical men by the "*penny wise*" folly of the Board of Guardians; and crowns the insult by the miserable and unnecessarily tedious manner in which the payments are made. It is high time that some Legislative measure was enacted to restrain the oppression which is daily victimising the honest practitioner from east, west, north, and south. [*Medical Times, December* 28, 1850.]

Hunterian Oration for 1851. Mr. R. A. Stafford has been appointed by the Council of the Royal College of Surgeons to deliver the annual oration in memory of John Hunter, on the 14th of February, 1851.

Parisian Medical Society. The following gentlemen have been elected office-bearers, for the next twelve months: Dr. J. W. Begbie, *President;* Dr. George Fleming, *Vice-President;* Dr. W. R. Sanders, *Secretary;* and R. Sarrell, Esq., *Treasurer.*

Self-Supporting Dispensaries. The tide has strongly set in against the establishment of these institutions in London. As the Society have not yet published their laws, nor a list of their office-bearers, we feel quite unable to speak for or against the present movement.

St. Mary's Hospital. The 28th Dec. was the last day on which candidates for the medical and surgical appointments at this institution were allowed to send in their applications. The officers to be appointed are, three physicians, three assistant-physicians, three surgeons, three assistant-surgeons, one physician-accoucheur, one surgeon-accoucheur, one aural surgeon, and one ophthalmic surgeon. The candidates are very numerous. For the office of secretary (lately filled), it is said that there were *three hundred* candidates! The emolument is £200 per annum.

Cholera in Jamaica. It is impossible to describe the desolation and dismay which the Cholera is causing in Jamaica. Not only are the medical practitioners in the island numerically inadequate for the fearful emergency, but we see by the local newspapers that opium and other necessary medicines, are not procurable in sufficient quantity.

APPOINTMENTS.

Bushnan, Dr. J. S., appointed Senior Physician to the Metropolitan Free Hospital, Devonshire Square.

Eddison, Booth, Esq., elected Surgeon to the Nottingham General Hospital, in the room of G. M. White, Esq., resigned.

Edwards, Vertue, Esq., appointed Resident Medical Officer to the Hospital for Consumption at Brompton.

Rowland, Dr., elected Assistant-Physician to the Charing Cross Hospital.

Simpson, Professor J. Y., elected President of the Royal College of Physicians, Edinburgh.

Williams, W. J., Esq., elected Resident and Visiting Surgeon to the Tower Hamlets Dispensary.

OBITUARY.

Allender, Dr. G., Assistant-Surgeon R.A., at Poona, in August last.

Andrews, Richard, Esq., Surgeon, late of Great Stanmore, Middlesex, at Uxbridge, aged 75, on 11th December.

Asbury, D., Esq., Surgeon, at Enfield, Middlesex, from the effects of a wound received while making a *post-mortem* examination, aged 23, on 25th October.

Brodie, Patrick, Esq., late Assistant-Surgeon, 13th Light Infantry, at Ordnance Place, Chatham, on 1st of December.

Calvert, Robert, M.D., Deputy-Inspector of Military Hospitals, at Camden New Town, on 12th December.

Courtenay, John Garnett, Esq., Staff-Surgeon, late Principal Medical Officer of New Zealand, on board the barque *Clara*, off the island of St. George, Azores, on 28th November.

Cunningham, Dr. Thomas, at Glasgow, of congestive apoplexy, on 10th October.

Davis, J. G., Esq., Surgeon, at Birmingham, from the effects of a wound received in making a *post-mortem* examination, aged 42, on 5th November.

Dorrington, Thomas, Esq., Surgeon to the Manchester and Salford Lying-in Hospital, at Manchester, aged 33, on 5th November.

Goss, John, Esq., Surgeon, at 36, Paternoster Row, aged 51, on 6th December.

Gordon, Dr. William, late of Montego Bay, Jamaica, at Perth, aged 42, on 24th October.

Guthrie, Dr. James, Assistant Colonial Surgeon, and formerly Assistant-Physician to the Royal Edinburgh Asylum, on board the barque *Atlantic*, at Trinidad, aged 34, on 26th September.

Heath, Dr. G. T., at Hoxton Old Town, aged 67, on 10th December.

Hume, Thomas, M.D., at Rose Bank, Hanwell, Middlesex, aged 81, on 21st October.

Jackson, Dr. Francis, at Dorchester, aged 43, on 14th November.

Ledingham, G., Esq., Surgeon, 83rd Regiment, at Poona, on 14th September.

Logan, Dr. D., Surgeon to the Nepaul Residency, in Bengal, lately.

Maitland, Dr. M., at St. Omer's, aged 81, on 26th November.

M'Lagan, Dr. John, at Demerara, on 11th October.
O'Connor, Dr. P., of fever, in Egypt, lately.
Philip, John, Esq., Assistant-Surgeon R.N., at Edinburgh on 13th December.
Ranson, John, Esq., Surgeon, at Ipswich, aged 33, on 27th October.
Royer-Collard, M., Professor of Hygiène at the Faculty of Medicine, Paris, aged 47, lately.
Saunders, James, Esq., Surgeon, at Foulsham, Norfolk, aged 67, on 12th Nov.
Simes, J. G., Esq., Surgeon, of Hungerford, aged 33, on 12th November.
Tanner, R. E., Esq., Surgeon, at South Molton, aged 56, on 2nd November.
Taylor, Dr. John, late Surgeon R.A., at 72, Upper Berkeley Street, Portman Square, aged 79, on 22nd November.
Walker, Dr. A., Surgeon in the Nizam's army, at Bolarum, of a fall from his horse, on 5th September.
Wheeler, James, Esq., Surgeon, at Wokingham, Berks, aged 84, on 15th Nov.
Whymper, Sir William, M.D., formerly Surgeon R.A., at Dover, aged 65, on 28th November.
Wilkinson, Dr. Charles H., in Pulteney Street, Bath, aged 87, on 15th October.
Wylie, Sir James, M.D., many years Physician to his Imperial Highness the Grand Duke Michael of Russia, at St. Petersburgh, aged 55, on 9th October (O.S.)
Yarnold, Dr. G., at Crookwell, Goulbourne, aged 38, on 20th May.

POSTSCRIPT TO MR. W. R. WILDE'S ARTICLE ON THE OPHTHALMIA OF THE TIPPERARY AND ATHLONE UNIONS.

The following was received too late for insertion in the paper on the above subject, given at page 17 of the present Number.

"I have just received a communication from Dr. Reardon, in which he informs me that the School in Bank Place—a very much more healthly locality than the Corn-store in Meeting-house Lane—has been converted into an Ophthalmic Hospital. 'There are there', he says, in his letter of December 15, 'very good airy wards, two large yards, and a garden to walk and play in. There is also an abundant supply of fresh water, and the dwelling-house is very comfortable. We have now 250 cases in town, most in the convalescent state, and 130 in the country. We have now very few bad cases, and the disease has, with rare exceptions, lost that intensity and destructive character, which in some constitutions, paupers in particular, does not yield to any treatment. I saw such vast benefit from removing the patients to the country residence at Castle Lloyd, as you recommended, and such a marked alteration in the nature and character of this disease, and the health and appearance of the patients generally, but especially the young female children, that I am fully persuaded it alone would remove the epidemic, and that little treatment, besides strict attention to ventilation, cleanliness, warmth, and diet, would be required. Knowing this, we have lately succeeded in getting another Auxiliary Workhouse, four miles from town, to which place we have just sent 130 convalescents. The bad cases, and those requiring constant treatment, are kept at Bank Place. Many of the cases supposed to be blind four months ago are now brightening up.' "

TO CORRESPONDENTS.

The Communications of Dr. C. J. B. Williams, Dr. George Johnson, Mr. W. R. Wilde, Mr. Hird, Dr. Cormack, Mr. White Cooper, etc., in our next and following Numbers.

Record of the Medical Sciences.

FEBRUARY 1851.—No. XXVI.

ORIGINAL COMMUNICATIONS.

ON THE PHYSICAL EXAMINATION OF THE ABDOMEN, IN HEALTH AND DISEASE.

By CHARLES J. B. WILLIAMS, M.D., F.R.S.

(Continued from page 6 of last Number.)

EXAMINATION OF THE ABDOMEN BY PALPATION.

The method of Palpation of the Abdomen is a subject of importance, and demands a few directions and cautions. The parts of the hands best qualified to feel are the palmar surfaces of the fingers, the pulpy portions of the last phalanx being endowed with the finest touch. But they should be flatly applied, at least at first; as nothing is more likely to start the abdominal muscles into rigid contraction than to poke them abruptly with the ends of the fingers. For the same reason, the observer should not be too much above the patient, and if the bed on which the patient is placed is low, the practitioner should sit or kneel beside it, in order to bring his arms and hands more on a level with the abdomen. It is equally obvious that the observer's hands should be comfortably warm; not only for the sake of the patient, but also because the touch is more sensitive in that condition. The posture of the patient generally best suited for examination is the supine, on a mattress or sofa, with the limbs lying straight, but without the least straining or muscular effort. It is often recommended to draw up the knees in order to relax the abdominal muscles; but this action is very apt to produce just the contrary effect, and further interferes with the free accessibility of the lower parts of the abdomen to the observer's hands. It is the great object, that whilst the body and limbs are so equally and completely supported as to be in a state of perfect relaxation, the whole abdomen shall freely admit of the application of the hands to every part, and in every direction. This further suggests, that in all cases requiring nicety in manipulation, the abdomen should be laid bare, the clothing sufficiently put out of the way, and that either the bed be narrow enough or the patient be moved to each

edge of it, so that the observer may be able, if necessary, to examine from both sides; this is especially requisite in the deep palpation to be described further on.

The kind of tact by which the different properties of *shape, softness* and *hardness, elasticity, weight,* etc., are distinguished, is so instinctive as scarcely to be capable of description; but it may somewhat guide a novice to say, that we trace the *shape* by applying the flat fingers and gently rubbing them over and between the prominences and depressions. We test the *softness* or *hardness* by pressing gently with the pulpy surfaces of the last phalanx on the successive parts over which the hands are passed; that which readily yields being soft, whilst the hard resists the pressure; the *elastic* opposes to it a spring, which, although yielding to strong pressure, sensibly pushes away the fingers as their application is relaxed. *Weight* is felt by lifting upwards a part, and observing what force is required to do this, and with what force it presses down again on the fingers as they are slightly withdrawn: trying the weight of part of the abdomen can be practised only in the lumbar and lateral regions in the supine posture; the anterior regions may be in a measure lifted and weighed by the hands, when the patient lies on his face, or sits leaning the body forwards; and this kind of examination is often of much importance in the diagnosis of ascites and solid visceral enlargements.

In the healthy state, the abdomen is in every region soft and moderately elastic; it feels smooth and uniform to the hand rubbed gently over it; when pressed superficially or deeply, its resistance is elastic and increasing with the pressure; when percussed on one side, no shock or fluctuation is felt on the opposite side; the different parts, when lifted, feel pretty equal in point of weight. This uniformity of soft elasticity represents the intestinal canal in its normal state, containing a moderate amount of gaseous, liquid, and semi-solid matter pretty uniformly distributed through it. As observed by inspection, so slight prominences may often be *felt,* corresponding with the stomach, the cæcum, and occasionally below the umbilicus; but these also feel soft and elastic as other parts, and do not detract from the generally equable character of the healthy abdomen.

Variations from this normal state of the abdomen may arise from alterations in the walls; and it will be well to advert to these before describing those caused by disease of the interior. Excess of fat gives a fulness which will feel firm and elastic, or soft and flabby, according to whether it is on the increase or on the decrease; but it may be known to be fat by its peculiar lumpy feel on the surface, so that it may be pinched up by the fingers and thumb; and in this way the thickness of the layer may be estimated. In the case of very fat paunches, there are masses of fat also in the omentum and mesentery; these form the large rounded prominence of the *pot-belly,* which renders the palpation of the abdominal viscera very difficult. In order to reach them in such a case, it is necessary to press firmly into the fat, and then to feel by moving the hand in a circular, or backward and forward direction; this may best be accomplished in the iliac and hypogastric regions, where the fat in the walls is not so thick as in the central regions of the abdomen. Where a corpulent person has lost much flesh, which is often the case in chronic disease, the loose

flabbiness of the pendulous abdomen may embarrass the practitioner; and the more so, as the fat which is left often has a granular or knotty feel, which might be mistaken for formations within the abdomen. These inequalities are to be distinguished by their being superficial, and capable of being grasped between the fingers and thumb; and the examination of the deep parts is to be effected by the hands steadily pressed inwards, pushing aside these inequalities, and rolling about or handling in divers ways the viscera underneath. Œdematous walls are to be treated in a similar manner, and are distinguished by their inelastic boggy feel, and pitting on pressure.

Permanent tension of the abdominal muscles is a common impediment to the palpation of the abdomen; it causes a feeling of superficial hardness, especially in the direction of the recti muscles.[1] If there be any doubt as to its seat, it may be dissipated by keeping the flat hand steadily and firmly applied with increasing pressure for a few minutes, whilst the patient's attention is taken off by conversation on another topic. The muscles will then be found either to relax altogether, or so much to vary their degree of tension as plainly to reveal the cause of the hardness. This test is equally successful, whether the muscular tension be caused by nervous irritability, or by actual pain or tenderness; for even in the latter case, flat pressure, gently and very gradually applied, may be managed so as not to increase the pain.

Extreme flaccidity of the walls of the abdomen might be supposed to remove all sources of fallacy in the manual examination of the abdomen; and it is, in fact, an easy matter to feel the place, shape, and consistence of almost every abdominal viscus: yet under such circumstances it is not very uncommon to find the pulsation of the abdominal aorta mistaken for an aneurism, and I have known the anterior convexity of the lumbar spine mistaken for a tumour. These errors arise from the observers not being aware how deep in the abdomen the hand reaches, and would be readily corrected by placing the other hand behind the back, and by thus feeling how small is the distance between the two hands.

Palpable signs of Disease in the Abdomen. *Fæculent accumulations* occur chiefly in the large intestines, and the lower part of the ileum; but the remaining portions of the small intestines are commonly more or less distended with gas. Hence the abdomen is generally enlarged; and the fulness feels more elastic around the umbilicus; and more resisting, yet not absolutely hard, in the iliac and hypochondriac regions. The course of the large intestine may often be traced; the greatest prominences being usually caused by the cœcum and transverse arch; and, if the abdominal walls are not tense, it is quite possible, by the pressure of the fingers, to distinguish the fæculent masses by, their substantial but inelastic feel, from the tympanitic contents of other parts of the intestine. If the accumulation be considerable, there is a very appreciable difference in the weight of different parts of the abdomen, as tested in the mode before described. If there be an excessive accumulation of air in the intestines, this dis-

[1] The tension of the rectus on the right side is often greater than that on the left, and I have frequently known it to be mistaken for enlargement of the liver. It does, in fact, sometimes arise from tenderness of the liver, which induces instinctively a firmer contraction of the muscles over it, to avert the pain of pressure.

tends them so much that the fæculent masses cannot be felt, and the whole abdomen has a tight elastic feel of rounded shape, but commonly showing more prominence in some parts than in others.

In *colic*, and constipation with severe *colicky pains*, there may in most instances be felt at parts, depressions, corresponding with contracted portions of intestines, which are hard and knotty, in comparison with the tympanitic elasticity of other parts. The abdominal muscles are often spasmodically contracted over these painful parts; but they become eased and relaxed under the steadily increased pressure of the flat hand. In these cases the weight of parts of the abdomen, as tested by lifting them when the patient is in the prone or leaning forward posture, is less than usual; the contents being proportionally lighter, and prevented from ponderating by the tight contraction with which they are bound.

The *tympanitis* of low fever and sinking states, of paraplegia from destruction of the lower portions of the spinal cord, or serious injury to its reflex function, is distinguished by the more uniform and less tense elasticity of the abdominal enlargement. The deficient tone of the intestines and abdominal muscles in these cases causes a larger and easier distension; and although the quantity of air pent up may be much greater, the tightness and resistance is less than in colic.

The presence of *liquid in the peritoneal sac* is capable of altering, in various ways, the palpable qualities of the abdomen. The size and shape may be felt to be changed in the same manner already described as obvious on inspection:—that is, the size is more or less enlarged, with bulging projections in the most dependent parts: the shape of the parts occupied with fluid is smoother, and more uniformly rounded than usual: and in extensive accumulations the surface may feel polished. But the resistance as felt by pressure is also distinctive: it is peculiarly soft, inelastic, and heavy. These qualities are most obvious where the abdominal walls are thin and flaccid; and under these conditions, there is no difficulty in detecting by the feel only, even moderate quantities of fluid in the abdomen. Ponderating to the most dependent parts, the fluid is to be felt in the flanks in the supine posture; at or near the umbilicus in the prone posture; in the iliac region when the patient lies on a side; and in the hypogastric region, when the patient sits, leaning forward. The soft and mobile yet weighty feel of these dependent parts, is to be compared with the more elastic and lighter resistance of other regions occupied by air-filled intestines; and by making the patient change his posture, allowing two or three minutes to give time for the subsidence of the liquid, we may have the further evidence that it is free in the peritoneal sac, if we feel it still showing itself in the most dependent parts. It does not often happen that there is enough liquid in the intestines to give anything like the same superficially soft and heavy sensation under the fingers; and when there is, it may be distinguished by its not thus gravitating from one region to another, as well as by its giving less sensation of superficial softness, and more of a gurgling or elastic feel, from the presence of air.

In proportion as the quantity of fluid in the peritoneum becomes greater, the distension of the walls also increases, and hereby the softness of the abdomen is diminished, whilst the weight is more pal-

pable. The liquid still gravitates in greatest volume to the lowest parts; but it also spreads more or less upwards in a layer between the viscera and walls of the abdomen; and gives a smoothness of surface, and uniformity of the peculiar weighty fluctuating resistance which characterizes its presence. So long as the distension is moderate, the air-filled intestines will usually float on the surface sufficiently to be in contact with the uppermost portion of the abdomen; and this will of course vary with the posture of the patient; that part can generally be distinguished by a delicate touch, which may be verified by the more obvious difference of percussion.

But there is a palpable sign of the presence of liquid, often manifest with a moderate degree of distension, more characteristic than any sign, not excepting those of fluctuation and percussion: I mean the striking of the fingers against the liver, or any other resisting body beyond the surface of liquid. It is plain that this sign will be most evident where there is considerable enlargement of the liver, spleen, or some other solid body; and as the liquid and solid become both more distinguishable on account of the contrast in the resistance which they respectively offer to the fingers, the sign serves to detect the presence of both. Thus a slight enlargement of the liver, reaching two or three inches below the margin of the ribs, may not offer resistance enough to be distinctly palpable by itself; but if there be a layer of serum interposed, and this be abruptly displaced by the fingers, they will strike the solid body with a distinct shock which will unequivocally prove the presence of both fluid and solid. It so happens that in a large proportion of the cases in which there is fluid effused in the peritoneal sac, there is also more or less enlargement of the liver, or some other large viscus; hence this sign becomes more generally useful. By its means I have been enabled to detect the presence of even thin deposits on the omentum and intestines, and of deeper seated mesenteric and ovarian tumours. Solid fæculent masses in the intestines may give a similar resistance to the fingers under a layer of fluid; and it is important that this source of error should be avoided, by having the bowels well cleared by aperients before the examination.

In manipulating for this sign of liquid and solid resistance, the fingers should be gently pressed more or less into the walls, and then a deeper impulse is to be abruptly made with their ends, so as to strike at any body which may offer resistance, and which then meets the stroke. Over an enlarged liver or spleen, this sign is best felt in the sitting or erect posture; or if the quantity of fluid be considerable, in the prone or leaning forward position. Indurations of the omentum and intestines are better detected when the patient lies on the back. In considerable enlargements of the spleen or left kidney, I have found this sign in the left lumbar region; but in other cases, the front of the abdomen is its usual seat.

On two occasions, through a modification of this sign, I have diagnosticated the presence of something adhesive on the striking surfaces. One was a case of ovarian tumour with ascites; the other, chronic peritonitis with enlarged liver. In both, the fingers readily felt the displacing fluid and the striking against the solid underneath; but on withdrawing the pressure, the surfaces in contact could distinctly be

felt to adhere for an instant before following the fingers, being retained by something adhesive. This sticking sensation was plainly felt by several students, to whom I pointed it out at the time, ascribing it to a coating of adhesive lymph. The post-mortem examinations did not occur till long after, but there was in both cases a deposit of false membrane on the surfaces which justified this inference. Probably this sign may prove useful in aiding to detect the presence of the low forms of peritonitis which frequently accompany abdominal tumours.

Fluctuation has long been recognised as a characteristic sign of the presence of fluid in the abdomen. It is commonly felt on applying the left hand on one side of the abdomen, and striking abruptly on the opposite side with the right hand, so as to direct the impulse towards the other hand. A wave is moved by the impulse, and rapidly passing to the opposite side, gives to the left hand the soft shock of fluid in motion. This wave-stroke is transmitted from one side to the other only when there is a continuous layer of fluid. If a fold of intestine rises to the surface in the centre of the abdomen, it intercepts the wave. Hence it often happens, where the quantity of liquid is moderate, that the fluctuation is felt at the lower part of the abdomen in the sitting or standing posture, and not when the patient lies on his back. The distinctness and character of the fluctuation vary according to circumstances that can be pretty exactly defined. The most remarkable degree is that produced when the abdomen contains much fluid, whilst the walls are thin and their tension is increased by a good deal of air in the intestines beneath the fluid. This adds to the elasticity of the walls; and wherever struck, they instantaneously transmit the shock with a kind of spring to every part of the surface; and so faithfully, that if a quick tattoo be played with the fingers on any part of the abdomen, each stroke can be felt in every other part with the greatest nicety. This highly vibratory fluctuation may therefore be considered a sign of flatus in the intestines, together with liquid in the peritoneum. Nor is this indication unimportant in its practical relations; for it leads to the use of mercurial purgatives and carminatives; which, by dispersing the wind, not only relieve the tension of the abdomen, but also bring the organs into a state more favourable for the absorption of the fluid.

When the distension of the abdomen depends on an excessive quantity of liquid alone, the fluctuation is still very distinct, but different in character from the last variety. It is less vibratory and spring-like, strikes the feeling hand with a deader, heavier shock, and requires a stronger stroke from the other hand to set it in motion. This kind of fluctuation, together with the peculiarly weighty feel of the abdomen in every part when lifted with the hand, and the equally dull sound on percussion, is a conclusive proof of the presence of a vast quantity of fluid, such as can seldom be removed without the operation of tapping. In fact, the same weight and pressure which we feel through the walls of the abdomen, is also oppressing and obstructing the organs of circulation, absorption, and secretion, to such a degree as to impede their functions, and to render them little amenable to purgatives and diuretics, which ordinarily excite their action. Hence, with such a state of abdomen, we find the urine and fæces

continue very scanty and vitiated, in spite of all the remedies we employ.

A moderate amount of liquid in the peritoneum requires more care to develope its fluctuation. It is most distinctly felt in the iliac regions when the patient is in the sitting or standing posture, which not only accumulates the fluid in greater quantity in these parts, but also thereby gives the requisite tension to the walls. If the liquid is in still smaller quantity, it may be insufficient to reach from one side of the abdomen to the other; and then it must be tried for in a more limited space, such as in hypogastric or in the one iliac region in the sitting posture. A delicate method of detecting small quantities of fluid by fluctuation, is by keeping the patient for some minutes lying on one side, then after he has turned nearly but not quite on his back, feeling for the fluctuation with the fingers lightly applied to the iliac region of the undermost side, whilst the other hand gently taps the flank or the hypogastric region; or the position of the feeling and striking hands may be reversed. By this expedient the fluid accumulates in contact with the walls where they are thin, and renders evident the gentlest fluctuation.

In feeling for such delicate and superficial fluctuation, it is important that the fingers should be very lightly applied; not pressed into the walls: otherwise the most sensitive parts of the fingers will be out of the reach of the wave. The soft and weighty feel of the liquid, as before described, may be taken in confirmation of the sign of fluctuation. The sensation of undulation itself, in fact, comprises more or less of the same impression of something heavy, soft, and in motion. It is important not to mistake for fluctuation an undulatory movement excited by percussion in the soft fat of the walls. This may be distinguished by its more uniform diffusion over the surface of the abdomen; by its not occurring more in dependent parts than in others; by its less liquid and weighty impulse against the fingers; and by its occurring chiefly in fat subjects, in whom the flabby adipose texture can be pinched up between the finger and thumb in such quantity as to prove that the walls are too thick to transmit any very superficial feeling of fluctuation from liquid in the abdomen. In fact, these cases of flabby fat abdomen are those in which small quantities of liquid are less readily detected by fluctuation, than by the comparatively greater weight and duller stroke-sound of the most dependent parts.

The discovery of a small quantity of liquid is of great importance in some cases; as for example, in distinguishing peritonitis from colic or neuralgic abdominal pain, and from tympanitis with which it is sometimes combined: and in detecting the first commencement of ascites, when remedies are more likely to be effectual than in the advanced stages. We are accustomed to watch for the signs of fluid effusion as indications of analogous conditions in the pleura; and by careful attention to the tests of palpation and percussion, these signs are not less available in the peritoneal cavity. It is true that we have not the striking contrast of the hollow-sounding lung, and the variations of voice and breath-sounds, to aid in their detection; but, on the other hand, we have the combined tests of percussion and palpation, and above all, we have in changes of posture of the patient the means of

concentrating the liquid in a dependent part, and of transferring it to another, in a degree unattainable with pleural effusion.

An obscure fluctuation may sometimes be elicited in the liquid contained in portions of intestine, in the urinary bladder, and even in the gall-bladder, and in cysts connected with the ovarium, the liver, the kidney, and other viscera; and if the quantity of fluid be considerable, it will manifest somewhat of its property of weight and soft resistance. But liquid thus contained may be distinguished from that free in the peritoneum, by its more obscure and less superficial fluctuation, and especially in its circumscribed position, which may not be the most dependent, and which is not materially changed with the position of the patient. It is quite possible to have combined, and to distinguish, the two kinds of fluctuation, the peritoneal, superficial, or gravitative, and the visceral, deep-seated, or circumscribed. The detection of the superficial fluid is even easier than usual, for the sac or cyst underneath raises the liquid, and makes it to spread more or less over its surface; which renders the fluctuation more obvious, and affords the additional criterion of the striking by displacement of the superficial liquid, as before described. The deep fluctuation is to be felt by first displacing the surface liquid by pressure, and with the hands thus deeply applied, succussion is attempted, and the contents of the cyst further felt. Change to the prone or leaning forward posture will commonly help in this investigation; as the cyst is often heavier, and, displacing the superficial fluid, comes in contact with the walls sufficiently to be manipulated. When the peritoneal fluid is scanty, the sac is more widely in contact with the walls, and may not be separable by any change of posture. In this case it may be of importance, in reference to an operation, to determine whether the sac adheres to the peritoneal walls; and in one such instance, a case of ovarian cyst, I was enabled to decide this point by the following expedient. The funnel end of a stethoscope being applied to the abdomen where the tumour was in contact with the walls, suction was used at the other end so as to make the walls adhere (by atmospheric pressure) to the instrument; it then became a means of separating the walls from the sac, the peritoneal fluid occupying the space; the presence of which fluid was determined by palpation around the part adhering to the stethoscope, and thus the non-existence of adhesions was proved. This patient was subsequently tapped; and when the fluid again accumulated, the surfaces could no longer be separated, adhesion having taken place around the puncture.

(To be continued.)

ON THE WEIGHT OF THE BRAIN AT DIFFERENT PERIODS OF LIFE, ETC.

BY THOMAS B. PEACOCK, M.D., Fellow of the Royal College of Physicians, and Assistant-Physician to St. Thomas's Hospital.

In the year 1846, I communicated to the *Edinburgh Monthly Journal of Medical Science* a series of observations of the Weight of the Brain and other organs of the body, together with various tables, compiled from the whole of the observations collected by the late Professor John Reid[1] and myself, while holding the office of Pathologist to the Royal Infirmary of Edinburgh. Since this time I have made the following observations, which, though comparatively few in number, yet being complete as to the weights of the brain and its several parts, and corresponding in every respect with the two previous series of observations collected by Professor Reid and myself, may form an useful addition to them. The present series contains also several weights of the Brain in young persons, in which the former were especially deficient. The weight employed, I need scarcely add, is avoirdupois.

TABLE I. WEIGHT OF THE BRAIN IN MALES.

The D in the column "Heart" indicates that the organ was diseased.

70	..	43 0	..	..	..	13 0D	Apoplexy.

The above observations are so few in number, that I have not thought it necessary to compile separate tables from them, more especially as it will be seen that they very closely correspond with the former much more numerous series. In the two following tables, however, I have presented the results obtained by calculating the whole of the data collected by Professor Reid, together with the present and former observations published by myself.

TABLE III. *Average Weight of the Brain at different periods of Life in Males.*

Ages.	Numbers weighed.	Average weight.
		oz. dr.
1 to 2 years	3	39 7

The extreme range in the weight of the encephalon of the adult male is from 34 oz. to 62 oz. 12 dr., the number of brains weighed having been 197; and in the adult female the range is from 36 oz. 12 dr. to 54 oz., the number weighed having been 107.

1. The average weight of the encephalon of the adult, as calculated from the observations contained in Tables I and II, is, in males, 50oz.6dr.; and in females 44oz. 7½ dr. The previous observations[1] gave an average of 50 oz. 3 dr. for the weight of the encephalon of the adult male, and of 44 oz. 14 dr. for that of the female. A similarly close correspondence will be observed on comparing the respective average weights of the several portions of the brain, as deduced from the two series of observations.

2. The observations now published show, with little exception, an increase of Weight in the Brain up to the period of adult age, but they are too few to satisfactorily illustrate this point. The tables compiled by Professor Reid,[2] that drawn up by Dr. Boyd[3] from a very extended series of observations conducted at the St. Marylebone Infirmary, and the tables in my former communication, founded upon the united ob-

[3] Wagner's Physiology, translated by Willis. 1844. Appendix, p. 700.

servations of Dr. Reid and myself, have so conclusively established the fact that the Brain does not attain its full development till from twenty to twenty-five years of age, that I should not have thought it necessary to insist upon it, had not Sir W. Hamilton[1] recently repeated, as fully established, the opinion which he formerly expressed,[2] that the Wenzels[3] were correct in stating that the brain attained maturity at or before the age of seven. To illustrate, therefore, the law of development of the brain, I have calculated the whole of the observations of Professor Reid and myself, and the results obtained are given in Tables III and IV.

From these tables it will be seen that the average Weight of the brain increases up to from twenty to twenty-five years age.[4] During middle life, or from twenty-five to fifty years of age, it retains about the same weight, and in after-life it declines considerably. It is true that some exceptions will be found to this rule among the separate observations, but though it occasionally happens that the brain of a young person may be found to equal or exceed in weight the average of adults of the same sex, such exceptions do not frequently occur, and can then only be ascribed to the organ having attained premature maturity, or, most generally, to the mode in which death has occurred. In cases where there is much obstruction to the circulation through the lungs during the last periods of life, the brain is found very much engorged, and though great care be taken to deprive it of the blood, it will still weigh heavier than if death had taken place under different circumstances. Thus it is that the brains of persons who have died shortly after the receipt of extensive burns, or in the collapsed stage of cholera, are found to be unusually heavy. Generally also persons who have died of acute diseases, have heavier brains than those who have long suffered from exhausting causes. To obtain, therefore, unexceptionable results, it would be necessary to calculate the average Weight of the Brain in persons who have died under precisely similar circumstances, and in observations so framed I am satisfied that the exceptions to the general rule would be very rare.

Sir W. Hamilton[5] states that he has "established, apart from the proof by averages, that the human encephalos does not increase after the age of seven at the highest. This has been done by measuring the head of the same young person from infancy to adolescence and maturity: for the slight increase in the size of the head after seven (or six) is exhausted by the development to be allowed to the bones, muscles, integuments and hair." It is, however, evident that this method of investigation can show only the period at which the brain attains its greatest bulk, and not that at which its development is completed; for every practical anatomist is familiar with the fact, that the density of the brain varies greatly at different periods of life. Calculations of the average Weight of the Brain afford the only means by which we can ascertain the period at which its full development is attained, and the changes which it undergoes during the progress of life.

[3] De penitiori structura cerebri Hominis et Brutorum, p. 267, fol. Tubing. 1812.
[4] It is probable, indeed, that there may be a slight increase beyond this period. In Dr. Boyd's table the weight, both in males and females, is greater at from 30 to 40 years, than at any other period of life.

ON SOME VARIETIES OF RENAL DISEASE, WITH ESPECIAL REFERENCE TO DIAGNOSIS AND PROGNOSIS.

By GEORGE JOHNSON, M.D., Fellow of the Royal College of Physicians, and Assistant-Physician to King's College Hospital.

None but those who have paid much attention to the Diseases of the Kidneys, and to the means of distinguishing one form of disease from another, can form an estimate of the true value of the information to be derived from a chemical and microscopical examination of the urine. It may safely be affirmed, that a microscopical examination of the urine is, in general, as necessary for the formation of a correct opinion in cases of renal disease, as a physical examination of the chest is for the exact diagnosis of diseases within that cavity. To determine the true nature of a disease in the kidney, and to form a probably correct judgment as to its course and termination, it is not sufficient merely to ascertain that albumen is present in the urine, that the specific gravity of the secretion is abnormal, and that moulds of the uriniferous tubes may be detected by the microscope. These signs may each and all be present in a given case; but a more precise examination of the circumstances is necessary for the formation of a correct diagnosis. The mere enumeration of these signs, such as is very commonly given in reporting cases of renal disease, will as little enable a practitioner to ascertain the true nature of disease in the kidney, as would a simple report of a patient having cough, with dyspnœa, expectoration, and a sound produced by the mixture of air and liquid in the air-tubes, suffice for the exact diagnosis of disease in the lung. In both instances, the signs must be exactly observed, and correctly reported; otherwise no sound opinion can be based upon them.

I have selected the following cases for publication, with a view to point out to my professional brethren some of the circumstances which require particular attention in the examination of cases of renal disease. It is well known that diseases of the kidney are amongst the most frequent of those which destroy life, and that some forms of renal disease are curable, while others are almost certainly fatal. In many of the most obvious circumstances, all the forms of renal disease are alike; and it is only by a careful attention to differences, which, however minute, may yet be readily and certainly appreciated, that we can hope to distinguish one disease from another, or to give a confident opinion as to the probable course and termination of a case.

The microscopical examination of the urine is much facilitated, by placing it in a conical glass, which will contain about three or four ounces. The fluid should be allowed to stand for a few hours before examination. I usually put it in the glasses at night, and examine it with the microscope on the following morning. This delay is not necessary if the sediment is abundant; but in many cases, when the sediment is small in quantity, it is quite essential that time should be allowed for its deposition to take place. A small quantity of the lower part of the liquid should then be removed with a pipette, and placed in a shallow cell for microscopical examination.

Case I. Acute Desquamative Nephritis—Urine very scanty, and highly Albuminous, with Epithelial Casts—Epileptic Convulsions and Coma—Recovery. I was called to see Ann Fers, æt. 54, as a dispensary patient, on the 6th Dec. 1849. I found her in a state of semi-stupor, and learned that she had been seized with a convulsive fit in the night. She had a wild, distracted look. The tongue was brown and dry. I subsequently learnt that, during the preceding six or seven months, she had lived very badly, in consequence of her husband being out of work. She had gradually become weak; and had restless nights, with frightful dreams, and spectral illusions. About a fortnight before I saw her, she had become much worse, with vomiting, intense head-ache, slight general dropsical swelling, pain in the back, and very scanty secretion of urine. She was ordered to have six leeches applied to the temples, and to take three grains of calomel every four hours.

In the course of the evening some urine was obtained. It had an abundant precipitate of lithic acid, and contained numerous *casts of tubes, with entire cells of renal epithelium;*[1] when boiled it became almost solid with albumen.

December 7th. In the morning of this day she was much the same. There had been no return of the convulsions; she had the same wild, and half-conscious expression of countenance; there was frequent vomiting. Eight ounces of blood were ordered to be taken, by cupping, from the lumbar region: two pills of colocynth and calomel to be taken immediately, and an effervescing draught every four hours.

December 8th. She was better; and said she was much relieved by the cupping; complete consciousness having returned soon after the operation. She had some sleep in the night; but was disturbed by horrid spectral dreams. Bowels freely opened; urine more abundant, and clearer; still some vomiting; tongue less dry, and cleaner. To take a mixture of sulphate and carbonate of magnesia three times a day.

From this time she steadily and progressively improved. The urine became more abundant; and all cerebral symptoms disappeared.

January 3, 1850. She began to take sulphate of iron with quinine three times a day. At this time the urine had a specific gravity of 1010; it was pale, abundant, contained a very few casts, entangling disintegrated granular particles of epithelium, the casts being of *small size:* albumen was still abundant.

February 4th. The urine had much the same characters. She was still pallid and feeble. The steel and quinine were continued.

March 7th. The quinine was omitted, and the dose of sulphate of iron was increased to two grains, with infusion of quassia, three times a day.

During the month of March she became much stronger, and in every way better. She gained flesh; and her face lost its pallor, and assumed a healthy hue. Towards the end of the month the urine was free from all trace of albumen, and contained no casts, nor renal epithelium. She remained under observation some weeks after this: her health continued good, and her recovery was complete.

Remarks. I reserve my remarks on the diagnosis and prognosis in this case, until I have referred to some other cases, with which it

[1] It is proposed to call casts of this kind "epithelial casts."

may be compared and contrasted. With reference to treatment, I have found, in other cases of acute desquamative inflammation of the kidney, that cupping in the lumbar region has afforded the same immediate relief to the cerebral symptoms, which was so striking in this case. There is no remedy in which, under the same alarming circumstances, I have an equal degree of confidence; and I feel assured that the abstraction of a small quantity of blood by cupping, from the region of the kidneys, is much more efficacious in removing cerebral symptoms, than any treatment directly applied to the head. In all cases of acute renal disease, whether occurring as a consequence of scarlatina, or from any other cause, when the urine is very scanty, and the patient complains of severe head-ache and drowsiness, there is much reason to fear that these symptoms may be followed by convulsions and coma; and unless the earlier symptoms are checked by a rigidly low diet, free purging, and the use of diaphoretics, no time should be lost in applying cupping glasses with the scarificatior over the kidneys. The congestion of the renal blood vessels is by this means lessened, the secretion is quickly increased, and the blood being thus purified, the cerebral symptoms are directly relieved. It must always be borne in mind, that an imperfect elimination of the urine will impoverish the blood more than the abstraction of a moderate quantity from the vessels, and that an attack of convulsions, if it do not end in fatal coma, may produce greater injury in the brain than all the powers of nature or of art can repair.

Case II. Occasional attacks of Gout—Chronic Bronchitis—Urine Albuminous, and containing Granular Casts—Death preceded by Convulsions—Chronic Desquamative Nephritis. Benjamin Hobday, æt. 47, a waiter, with sandy hair and pallid skin, was attended by me as a dispensary patient in Jan. 1847. Was in the habit of drinking freely, and had several times had gout. About three months before I first saw him, his wife had observed that his abdomen became tumid, and his face rather puffy; this soon subsided, and there was no subsequent appearance of dropsy.

This present illness began, six weeks before I saw him, with cough and mucous expectoration. There was large crepitation over both sides of the chest. He was losing flesh; he always appeared dull and heavy; and his tongue was dry and brown. He took an antimonial mixture without relief. The urine was scanty and high coloured; it contained a small quantity of albumen, and numerous *dark brown casts, apparently composed of disintegrated epithelium.*[2] No blood corpuscles were observed. The specific gravity of the urine was not noted.

January 25th. He had several attacks of convulsion, in the intervals of which he lay muttering and insensible. On the following day he died.

Post-mortem Examination. The brain and its membranes appeared quite healthy. The lungs contained scattered crude tubercles, and were much engorged and carnified. The only organs decidedly diseased were the kidneys; and they presented the characteristic ap-

[1] The term "granular casts" sufficiently expresses the character of these bodies.

pearances of chronic desquamative nephritis. The cortical substance was wasted, and its surface irregular and granular. Some tubes contained an excess of cells, differing little in appearance from the normal epithelium; while the greater number of the tubes contained the same granular material, which, when washed out, had evidently formed the casts which were observed in the urine during the life of the patient. Other tubes, again, were pale and transparent, being composed only of basement membrane; the epithelial cells, which probably had first become disintegrated, having been washed away by the current of liquid passing through the tubes.

Remarks. The preceding case is an example of the form of renal disease, which is very commonly observed in gouty subjects. The blood is contaminated by certain morbid matters, as a consequence of the gouty diathesis; the kidneys make an effort to eliminate these materials; and, in doing so, their secreting cells undergo a modification. They become opaque and granular, then completely disintegrated, and subsequently are washed away, leaving the tubes denuded. After the destruction of the secreting cells, the tubes waste, in consequence of the removal of the vital attractive influence of the cells upon the blood.[1] The cortical substance thus becomes irregularly contracted and granular.

There is one point of view in which it will be instructive to compare the case of Hobday with that of Fers. It might have happened to me to have seen Hobday for the first time, as I did Fers, soon after the first attack of convulsions. The question arises,—were there any distinctive signs in the two cases, which would have suggested, in the one case, a much more hopeful prognosis than in the other? This is clearly a question of great practical importance, and one, too, which happily admits of a decisive and satisfactory answer. In the case of Fers, the urine contained what I have called "epithelial casts", that is, fibrinous matter entangling *entire epithelial cells;* and these, with albumen, and very commonly blood, in the urine, indicate a recent acute disease in the kidney. In such a case, there is much reason to expect recovery, if we can succeed in warding off the urgent symptoms induced by the poisoned condition of the blood, consequent on the impaired excretory function of the kidney. In the case of Hobday, the appearances were very different. The casts in the urine were composed of *granular particles of disintegrated epithelium.* My observation has taught me to associate this form of cast with a chronic disease in the kidney. Where these casts have been observed in the urine during life, the kidneys will be found after death more or less wasted, sometimes extremely so, and the tubes will be in the condition described in the case of Hobday, some being entirely denuded, and others filled either with disintegrated epithelium, or with cells differing more or less from the normal epithelium. This chronic form of disease may have advanced to the extreme stage of atrophy before the occurrence of any urgent symptoms. Amongst the most common and most serious of its ultimate consequences, is an attack of convulsions,

[1] On this subject see the author's paper "On the Proximate Cause of Albuminous Urine and Dropsy", in volume xxxiii of the *Medico-Chirurgical Transactions;* also on the "Inflammatory Diseases of the Kidney", in volume xxx.

recurring more or less frequently. Now if, in a case in which convulsions have once occurred, we find the urine albuminous and containing the "granular casts" described above, we must be prepared for a recurrence of the attacks, and for the probability of a speedily fatal termination.

I must beg my readers to bear in mind, that the preceding remarks relate to cases in which convulsions or coma, or other serious mischief, have resulted from deficient renal excretion, such symptoms affording evidence of extensive disease in the kidney, which, if it have gradually advanced to that degree by a process of chronic inflammation, is but very little under the influence of treatment. The "granular casts", *per se*, indicate merely the *form* of disease, and not the stage of its progress, or the degree of mischief which it has produced. Still the existence of these casts is a very important sign, being present from the very commencement of the chronic desquamative process. They may often be detected before the disease is so far advanced as to render the urine albuminous; and at this early stage of the disease we have most reason to expect that our remedies will be successful. Further, the proportion of this granular material in a given quantity of urine, affords an index of the rate at which the disease is progressing. The granular casts are composed of disintegrated epithelial cells, which, being thus shed, appear in most instances not to be reproduced; the greater, therefore, the quantity of this material discharged with the urine, the more rapid must be the destruction of the secreting tissue of the kidney, and the more speedy will be the occurrence of urgent symptoms from suppressed secretion. In the extreme stages of chronic desquamative disease, the granular casts sometimes disappear more or less completely, and are replaced by casts of a very different kind, as will be seen in the history of the succeeding case.

It may be well to remark in this place, that there are at least two circumstances, under which the occurrence of granular casts does not indicate the chronic disease above alluded to. A moderate amount of care will, however, in either case prevent an error of diagnosis. *First*, after an attack of acute desquamative nephritis, it commonly happens, that for some days, while the urine is returning to its normal condition, casts composed of disintegrated epithelium and blood are discharged with the secretion; these gradually diminish in number, and soon entirely disappear. *Secondly*, after an attack of renal hæmorrhage, some blood, which has remained in the tubes, becomes disintegrated and washed out in the form of granular casts, which, however, have generally a yellowish-brown blood-colour, and this would suffice to distinguish them from the epithelial granular casts. In addition to this, the occurrence of hæmaturia would be almost conclusive evidence of the non-existence of chronic desquamative nephritis, the extremely thickened condition of the blood-vessels in that disease rendering the occurrence of renal hæmorrhage, at least in the advanced stages, a very rare accident.[1]

In one case of scurvy, I observed yellowish-brown granular casts, which I at first supposed to be indicative of chronic desquamative

[1] Upon this point, see the author's paper, before alluded to, in *Med.-Chir. Trans.* vol. xxxiii.

disease, but which I subsequently found to be composed of disintegrated blood-corpuscles and fibrine. The man quickly recovered under the care of Dr. Todd, in King's College Hospital, and, in a few days, the casts entirely disappeared.

Case III. Acute desquamative Nephritis passing into chronic desquamative disease, with granular Casts in the Urine, and subsequently a waxy Deposit in the Kidney; with "Waxy Casts" in the Urine—scanty Secretion—Pericarditis—Pleurisy—Death. John Revels, aged 30, a labourer, of temperate habits, but much exposed to wet and cold in his work. About seventeen years ago, he was ill for a month with dropsy, but recovered completely. His present illness began about seven or eight months ago, after getting wet through while at work, and standing for some hours in his wet clothes. After this, he felt "chilly, and shivering and miserable"; the breathing soon became oppressed; and he began to suffer from head-ache, which had continued until the present time; he had gradually grown pale and weak, and had lost flesh; there had occasionally been slight swelling of the face and hands. He had suffered much from dyspepsia, and once had bleeding from the nose to a considerable extent, since which he had discontinued his work, on account of weakness. He reported of the urine, that at the commencement of his illness, it was very high-coloured—"like porter"; and that it was at the same time scanty; but that it soon recovered its natural appearance, and became more abundant than natural. He had sometimes got up four or five times during the night to pass water, and had passed as much as three quarts in twenty-four hours.

This sequence of phenomena is very commonly observed in cases of acute desquamative nephritis; the urine being at first scanty, and darkly tinged with blood, and shortly afterwards becoming paler and much more abundant than in health. I have suggested an explanation of this abundant secretion of urine in a paper "On the Inflammatory Diseases of the Kidney", published in volume xxx of the *Medico-Chirurgical Transactions.*

The preceding narrative brings the history of the patient to the 17th Nov. 1847, when he first came under my observation. It was then noted, that he was of middle height, muscular, but the muscles flabby; hair light; face and lips very pallid. He complained chiefly of weakness, and slight headache; his breath was short, on making any exertion; the sounds of the heart were normal. Pulse 88; skin cool; tongue clean; no thirst; appetite good; but he was much distressed by flatulence for about two hours after eating. This is one of the most common and distressing symptoms in cases of chronic renal disease. He passed about four pints of urine in twenty-four hours, of specific gravity 1012. It deposited a rather abundant dense whitish precipitate, composed of dark granular casts (probably disintegrated epithelium), with some scattered renal epithelium; there was no blood nor crystals; albumen was present in small quantity. The nature and the amount of the sediment at this time indicated rapidly progressing chronic desquamative disease. (See p. 113.)

November 20th. I admitted him into King's College Hospital, under

the care of Dr. Todd. On the 24th and 26th the urine was again examined, with the same result as before.

December 11*th*. The urine had the same characters as before. During the last twenty-four hours he had passed four pints (16oz.), and 4 oz. He was getting worse; his face was pale, and puffed; the countenance was heavy; he complained of weakness and drowsiness, and occasionally vomited after his meals.

December 16*th*. I now first observed what I propose to call the "waxy casts"[1] in the urine, mixed with the dark granular casts before mentioned. The waxy casts were of a yellowish white colour, very much resembling wax; they had a well-defined outline, and a diameter of about 1-400th, or 1-500th of an inch; they did not entangle epithelial cells; but some contained, here and there, a few small nuclei, about the size of blood corpuscles.

December 20*th*. The waxy casts were more numerous in proportion to the granular casts. The urine had a specific gravity of 1012; albumen was moderately abundant.

December 27*th*. The legs were swollen, and pitted on pressure.

January 1*st*, 1848. He had shortness of breath, and uneasiness about the heart. Pulse 96.

January 4*th*. The countenance was anxious; a loud double friction sound was heard over the heart. Pulse 120. Respirations 32. He passed less urine, perspired freely, and vomited frequently.

January 5*th*. Feeling that he was beyond hope of recovery, he insisted on being removed to his own house, where he gradually sank. The urine became very scanty. A catheter was once passed, under the idea that the secretion was retained in the bladder; but scarcely any was found there. At length he became delirious; and died on the 11th January.

Post-mortem Examination two days after Death. The body was well-formed, and muscular, very little emaciated; the skin was very pallid. The pericardium contained a moderate quantity of serum. The surface of the heart was roughened with recent lymph; the heart was larger than usual; the left ventricle was dilated, and its walls were very thick; the valves were all healthy. There was some lymph on the right pleura, in contact with the pericardium. The lungs were congested, but in other respects healthy.

Kidneys. The cortical substance was thinned, and contained a yellowish-white, firm, waxy material, which, on the surface, formed projecting granules, varying in size from a pin's head to a large pea. In parts, where this material was most abundant, the tissue was anæmic; where it was less abundant, the vessels were congested. On the surface of one kidney there was a cyst, of the size of a large pea. Some of the tubes were crowded with epithelium, some contained granular particles of disintegrated epithelium, others were denuded; and others, again, contained the same wax-like material which had formed the casts already described as existing in the urine. At the same time, I noted an appearance of fibrous tissue, which I then supposed to be the result of conversion of the basement membrane of the tubes into

[1] The term *waxy* is applicable only to the appearance, and not to the chemical composition of the material, which is probably of a fibrinous or albuminous nature.

fibrous tissue, but which I have since ascertained to be hypertrophied arterial walls. With reference to this point, I must again refer to my paper in the thirty-third volume of the *Medico-Chirurgical Transactions*.

Remarks. This case was evidently, at the commencement, one of acute desquamative nephritis. If at this time the patient had been subjected to proper treatment, which would have implied a temporary discontinuance of his work, and a strict avoidance of exposure to wet and cold, there is reason to believe that he would soon have been restored to health. The poor man, however, did not apply for assistance until the disease had become chronic, and had advanced beyond the stage at which treatment could be of any avail. The most interesting point in this case, is the observation of the first appearance of the "waxy" casts in the urine, their mixture with the granular casts, and subsequently the increased number of the former in proportion to the latter; their appearance in the urine being, doubtless, simultaneous with the deposit of the wax-like material in the kidney, and this material being probably secreted by those tubes which had previously lost their epithelial lining.

The following case, in some points, resembles that of Revels; but in other respects it differs materially. It possesses a peculiar interest.

Case iv. Numerous attacks of Gout—Chronic Desquamative Nephritis—Urine Albuminous—a very few Waxy Casts — almost Complete Suppression — Urinary Tubes Denuded — Renal Arteries and Malpighian Capillaries thickened. Thomas Hewson, æt. 49, a coachman, had always drunk freely of porter,—on an average half a gallon daily. At the age of twenty-five he had inflammation of the chest; and during this attack he was first seized with gout in one great toe. About three or four years after this, he had a second attack; since which the attacks had returned with increased frequency, and had, at different times, affected almost every joint. For several years before his death, he was disabled by gout for about nine months in each year; his diet had consequently been very poor. This is one amongst a great number of instances, with which I have met, in which a labouring man has brought upon himself and his family long-continued severe suffering and privation, by an intemperate use of London porter. I attended him frequently as a dispensary patient, for attacks of gout, before I had any suspicion of renal disease.

June 7th, 1849. I examined the urine. It had a specific gravity of 1015; it was pale, and deposited a very slight cloud, containing a few well-defined "large waxy casts", similar to those observed in the preceding case, but very much less numerous. Scarcely a particle of renal epithelium could be seen. The urine contained a large quantity of albumen, becoming almost solid when boiled. The patient was of rather small stature; his hair and whiskers were sandy; his face pallid; he was considerably emaciated. During the last two years, the legs had occasionally become œdematous after sitting up; and the face had sometimes been slightly swollen, but there was now no appearance of dropsy. A short time since he had an attack of gout; but he now complained chiefly of weakness, which confined him to bed.

The joints were free from deposits and distortions, except a slight contraction of the fingers of one hand. His wife observed that, during the earlier attacks of gout, the urine was generally high-coloured and turbid, but that latterly it had remained pale and free from deposit. He was ordered to take small doses of tincture of sesquichloride of iron.

June 18th and 27th. The urine was examined, with the same results as before.

July 3rd. During the last fortnight, he had become deaf. He was much changed in appearance; he sometimes appeared confused in his intellect; the limbs frequently moved in a chorea-like manner. He was very pale and thin, and complained of an acrid taste in the mouth. His breath was fœtid; he had occasional bleeding at the nose; there was frequent vomiting. The urine was scanty; the quantity obtained was insufficient for ascertaining its specific gravity; it was highly albuminous, and threw down a rather copious dense precipitate, of a whitish brown colour, composed of numerous *waxy casts, varying in diameter from* 1-375 *to* 1-750 *of an inch.* There was no epithelium, either entire or disintegrated. He was ordered to have an effervescing draught every four hours.

July 7th. He was worse; had frequent vomiting, and severe headache. He had passed only about two ounces of urine during the last twenty-four hours. It was light coloured, very albuminous, and had a very slight sediment, containing traces of the same casts as before. The effervescing draughts were repeated; and a quarter of a grain of elaterium was prescribed, to be taken immediately.

July 10th. He was much the same. The urine amounted to about four or six ounces in twenty-four hours. Yesterday its specific gravity was 1016; this day it was 1019; it was pale, highly albuminous, and had a very scanty sediment, with traces of the same casts as before.

July 14th. He was much the same, but more exhausted, and very pallid; the skin was cool. He became suddenly faint; and died soon after my visit, retaining his consciousness and power of speech until within a few minutes of his death.

Post-mortem Examination on the fourth day after Death. The weather being warm, and putrefaction having commenced, the kidneys were removed by an opening in the abdomen; no other parts were examined. Both kidneys had much the same appearance. Their size was rather less than normal; one weighed 3½oz. The surface was smooth. In the cortical substance of one, there was a cyst about the size of a horse-bean. They were slate-coloured, from incipient decomposition. The chief structural change visible to the naked eye, consisted in the absence of the usual lobular appearance on the surface. The cortical substance was rather thin; but an unpractised observer might have pronounced the kidneys healthy. On a microscopic examination, the Malpighian bodies appeared very conspicuous, while the tubular structure was confused and indistinct. After the addition of acetic acid, the tubes became much more distinct; many were denuded and atrophied. Scarcely one could be seen with the normal epithelial lining; some contained oil; others, brown granular particles of disintegrated epithelium; and a very few contained the white waxy material, which had formed the casts observed in the urine during

life. In consequence of the atrophy of the tubes, the Malpighian bodies seemed relatively more numerous, and closer together than ordinary; they were not perceptibly enlarged; one of the largest measuring 1-75th of an inch. The Malpighian tufts were of a dull white colour; the surface of the vessels was smooth, their coats thickened, their canals clearly visible in many instances, especially after adding acetic acid, which also brought into view the blood-corpuscles in their interior. The coats of the arteries were hypertrophied; and the canal of one contained some small masses of oil.

Remarks. There can be little doubt that the morbid process, in the case of Hewson, was essentially the same as in that of Revels; and that the urine, if examined at an earlier period of the disease, would have presented the granular casts, which an examination of a great number of cases of this disease has shown to be quite characteristic. In this case, the desquamative process had continued until nearly all the tubes had lost their epithelial cells; and, then, as a necessary consequence, secretion was almost completely arrested. There was one remarkable difference between the two cases; the wax-like material, which was deposited so abundantly in the kidneys of Revels, was, in the case of Hewson, only just sufficient to afford the data for a correct diagnosis and prognosis.

Immediately after the case of Hewson, another essentially like it occurred to me in a woman named Brooks. The urine had the same characters, and contained the peculiar large waxy casts. The kidneys presented the same general and microscopical appearances.

When the urine is pale, and of rather low specific gravity, containing a large quantity of albumen, with a scanty sediment, composed of the peculiar large waxy casts, as before described, with little or no epithelium, either entire or disintegrated, it may be almost certainly inferred that the chronic desquamative process has destroyed the secreting cells of the kidney; and that if urgent symptoms of suppressed secretion are not already present, they will very speedily appear.

I have several times spoken of the waxy casts as being "large", and I have given the diameter of those observed in the urine of Hewson. My reason for doing so has been, that as the diameter of these casts was equal to the average diameter of healthy kidney tubes, *their size was sufficient evidence that the tubes, in which they had been moulded, had no epithelial lining, and were composed only of basement membrane*, as the post-mortem examination of the kidneys proved to be the case.

I will now give the particulars of a case in which what I propose to call "*small* waxy casts" were observed, and which formed the ground of a favourable prognosis, which the result proved to have been correct.

Case v. Intemperate Habits with an insufficiency of nutritive Food—general Dropsy—ecthymatous Eruption over the Body—Urine highly albuminous, and containing "small waxy" Casts—Recovery. George Henry Lewis, aged 45, of intemperate habits, much reduced in circumstances, and latterly living very badly, was admitted into King's College Hospital, under the care

of Dr. Budd, on the 6th June 1849. He was suffering from general anasarca and ascites in a very great degree, and his body was covered with an ecthymatous eruption. He was very pallid; his breathing was difficult, and accompanied by a wheezing sound. The dropsy had appeared two weeks before, and the eruption a month earlier. The sounds of the heart were normal. The urine was scanty, rather light-coloured, somewhat cloudy, of specific gravity 1012, becoming almost solid with albumen when boiled. After standing, it deposited a pretty abundant whitish dense precipitate, chiefly composed of *transparent waxy casts, about one-thousandth of an inch in diameter.* Very few epithelial cells were seen, and no blood-corpuscles, or very few.

Few, probably, who saw the miserable condition of this poor man at the time of his admission, would have given a favourable prognosis; but after a microscopical examination of the urine, I ventured to suggest to my friend Dr. Budd the probability of his patient's recovery, for the following reasons. The appearance of the casts seemed to indicate merely congestion of the Malpighian capillaries, and an absence of disease in the epithelial cells. The diameter of the casts proved that they were moulded in canals lined by epithelial cells; in this respect forming an instructive contrast with the casts in Hewson's case (p. 117). The almost entire absence of epithelial cells from the urine showed that the secreting structures were but little involved; since any morbid matter in the blood, injuriously affecting the secreting cells, would have produced a desquamation of these structures. The inference was, that the blood was in such a morbid state as produced congestion of the Malpighian capillaries, while it affected but slightly, if at all, the secreting cells of the kidney. As a consequence of the congestion, coagulable matter with serum escaped from the Malpighian vessels, and, after being moulded in the tubes, was washed out with the urine, forming the "small waxy casts" already described.

He was first put on milk diet, and was ordered to have a tepid bath every morning, and to take small doses of solution of citrate of ammonia, with fifteen minims of ipecacuanha wine, every six hours. He began to improve almost immediately. It may be well to mention here, that for several years he had been subject to epileptic fits, which returned with increased frequency while he was suffering from the dropsy.

The urine was frequently examined, and its condition carefully noted. The albumen continued very abundant for about six weeks. The quantity passed in twenty-four hours did not exceed one pint when he was first admitted, but soon became more abundant, and for some days exceeded the normal quantity. Thus, on the 18th June, it measured five pints. In this increased flow of urine, following upon a scanty secretion, the case resembled one of acute desquamative nephritis (see p. 114).

June 25th. It was now first noted, that some of the casts entangled a few oil-globules, and here and there appeared a cell containing oil. These appearances continued for about three weeks, and occasioned some anxiety lest the kidneys should undergo fatty degeneration; the more so, as the albumen was still very abundant.

About the middle of July, the oil was evidently diminishing, and the casts were less numerous; but the albumen was as copious as at the commencement. The specific gravity of the urine was 1014.

July 26th and 27th. The albumen was reported to be much less, so that there was scarcely more than opalescence when the urine was boiled. The urine was clear; there was no cloud or sediment after standing, nor anything visible by the microscope. In the meantime, the eruption and the dropsy had entirely disappeared, his appetite and strength had returned, and the pallor of his face had been replaced by a healthy hue. Since the 26th June he had been taking steel, sometimes in the form of citrate, and occasionally in that of tincture of the sesqui-chloride.

July 30th. He was progressing favourably; had improved in all respects. The bowels were regular; the tongue clean; he slept well. The urine was scarcely albuminous.

August 1st. He left the hospital without leave, and has not since been heard of.

Remarks. It is instructive to compare the history of this case with those of Revels and Hewson. In appearance, the condition of Lewis, when he first came under observation, was much more desperate than that of the other two. The microscope was the only means of determining that the probability of recovery in each case was precisely the reverse of that which, to a superficial observer, it might appear to be.

I will conclude this communication with a few remarks on the Diagnosis of Fatty Degeneration of the Kidney; one of the most intractable, and unhappily one of the most frequent of the forms of renal disease.

The urine, in cases of fatty degeneration of the kidney, has characters sufficiently distinctive to render the diagnosis a matter of ease and certainty. It is commonly of a rather pale, yellowish colour. When first passed, it is clear; but, after standing for some hours, it usually deposits a light, cloudy sediment; sometimes, in the early stages, the urine has a dark smoky colour, from containing blood. The quantity secreted is less than normal, and its density in most cases exceeds the healthy standard; it is by no means unusual to find the specific gravity ranging from 1025 to 1030. The albumen is generally very abundant, so that, when boiled, the urine becomes almost solid. On a microscopic examination of the cloudy sediment before mentioned, there may be seen transparent casts of rather small size, in many of which are entangled oil-globules of various sizes, also cells containing oil-globules in greater or less abundance. There are besides scattered cells, more or less completely filled with oil. I might transcribe from the pages of my note-book many cases, in which the urine has presented more or less of the characters here described, and in which not one of the patients has recovered. The majority of these cases have terminated fatally; while, in a few instances, the symptoms continue in a greater or less degree; the urine continuing highly albuminous, and presenting unequivocal microscopical evidence of the true nature of the disease. For the purposes of prognosis, it is as important to distinguish between a case in which the urine presents the characters here described, and a case of simple desquamative nephritis, as it is to distinguish tubercular disease of the lung from acute pneumonia or bronchitis.

Now, since the prognosis in a case of confirmed fatty disease of the kidney is thus unfavourable, it is important that all who examine the

matter should clearly understand that albuminous urine may contain a certain amount of oil, entangled in fibrinous casts, or enclosed in epithelial cells; and yet the disease may be of a simple nature, and may speedily terminate in recovery. It is very common to find small quantities of oil in the casts and in the cells, after a simple inflammation of the kidney has existed for three or four weeks. Now, since an inflammatory disease does in some instances become chronic, and terminate in confirmed fatty degeneration, the appearance of any oil in the urine must occasion a certain degree of anxiety, lest it should increase in quantity, and take the place of the simple inflammatory products. In the case of Jervis, it will be remembered that oil was seen in the casts and in cells, that it continued for several days, and then entirely disappeared simultaneously with a rapid decrease in the quantity of albumen. The following brief notice of a case will serve as an example of what may frequently be observed.

Case vi. Acute desquamative Nephritis, with general Dropsy; Urine scanty, highly albuminous and containing fibrinous Casts, Epithelium and Blood—subsequently oil in the Casts and Cells—Complete Recovery. John St. Ledger, aged 49, a billiard-marker, applied to me at the Dispensary on the 12th April 1847, and gave the following account of himself. During the period of Lent, he had fasted very rigidly, *i. e.* during four days in the week he took only one meal a day, composed of fish, with milk and potatoes; during the remaining three days he took animal food as usual, perhaps rather in excess. Under this plan of diet he found himself getting thin and weak, and he became very dyspeptic and flatulent after his meals. On Easter Monday, April 5th, he felt drowsy, and had muscular pains. The next day, dropsical swelling appeared, and the urine was very scanty. He continued to get worse until the 12th April, when he first came under my notice.

There was then slight general dropsy, head-ache, and drowsiness; the urine was scanty, high-coloured, and very albuminous. It presented the characteristic appearances of simple acute desquamative nephritis; containing fibrinous casts, entire epithelial cells, and blood corpuscles. During the first few days he was much benefited by cupping, warm baths, purging, and diaphoretics.

A careful microscopical examination of the urine was made almost daily. Its characters remained the same until the 29th April, when, for the first time, it was seen that many of the epithelial cells contained oil-globules. At that time, I knew much less of the history of this disease than I now do; and I quite despaired of my patient's recovery. Day after day the oil was visible, some cells being completely filled with it; but, at the same time, *by far the greater number of cells were entirely free from oil*, and this is the circumstances which, with my present knowledge of these cases, would have suggested to me a favourable prognosis. Early in the month of May the dropsy disappeared, but the patient continued very weak and pallid.

May 6th. He began to take a draught three times daily, consisting of diluted nitric and diluted hydrochloric acids, ten minims of each, in infusion of quassia.

May 31st. The above medicine was discontinued, and he took an

ounce of compound mixture of iron three times daily. Soon after the change of medicine, he began to gain strength, and to improve, in every way, very rapidly.

June 14th. The quantity of urine was three pints in twenty-four hours; of specific gravity, 1017; the colour was natural, the albumen much diminished. It contained a few casts, with epithelium more or less disintegrated, and scarcely a trace of oil.

At the beginning of July, the urine was free from albumen, and presented no trace of oil, but a very few casts with disintegrated epithelium; he was gaining strength, and was much improved in appearance. Once after this, there was a temporary return of albumen, but it soon disappeared, and he completely regained his health and strength. He has occasionally since been under my care for trifling ailments; I have several times examined the urine, and have found it, in every respect, quite healthy.

3, Woburn-square, Dec. 31, 1850.

ON THE INHALATION OF VARIOUS MEDICINAL SUBSTANCES.

By JOHN SNOW, M.D.

The following are the chief reasons why it may be desirable to give medicines, in some instances, by Inhalation, in preference to the more ordinary method by deglutition.

1. As the influence of the medicine appears immediately, and a greater surface is offered for absorption, a larger dose may be given, and a more sudden and profound effect produced on the economy than it would be safe, or, in some cases, even possible to produce in any other manner. An instance in point is the insensibility induced by chloroform and ether.

2. The process of digestion is less interfered with, than by taking medicines into the stomach.

3. Many medicines which have a disagreeable taste—as turpentine, creasote, and camphor—are not unpleasant when inhaled in the form of vapour.

4. Agents, such as benzoic acid, and some of the gum-resins, which are believed to exert a local action on the mucous membrane of the air-passages, may be expected to have a greater effect when inhaled, than when they are taken into the stomach in the same doses, and reach the lungs only through the circulation.

5. Some agents, as chlorine and ammonia, have a local action when inhaled, which they could not exert if exhibited in any other way.

It was almost solely with a view to their local action that medicines were inhaled, prior to the discovery at Boston, in America, of etherization, which established a new era in inhalation; and even at the present time, with the exception of ether and chloroform, hardly any medicines are exhibited by inhalation, unless in affections of the lungs; although there evidently ought to be no such limitation of the practice.

It must be acknowledged in the outset, however, that it is a much less simple and easy matter to have medicines properly inhaled, than to direct them to be swallowed; and it is the object of the present communication rather to attempt the removal of difficulties, and to point out the physical conditions under which certain medicines can be inhaled, than to detail the results which have been obtained by inhalation.

Owing to neglect of the physical properties of a medicine, it has sometimes been supposed to be inhaled, when in fact it was not, unless in a quantity almost infinitesimal. It has not been unusual, for instance, to direct a drachm or two of tincture of hyoscyamus or conium to be put into half a pint or a pint of hot water, in order to be used for inhalation. Now the virtues of an infusion of these plants remain in the extract, after the water is all evaporated at a moderate temperature; and if the patient had inhaled day after day from the same water (having it made hot for the purpose), till it had all been consumed, the medicine would have been found at the bottom of the vessel in the form of an extract, to which water might have been added for the process to be commenced afresh. It is obvious, therefore, that any effects which have been produced by inhaling in this manner, were due either to the vapour of the water, which is very beneficial in irritable states of the mucous membrane, or to physical causes depending on the construction of the inhaler, and the mode in which it was used.

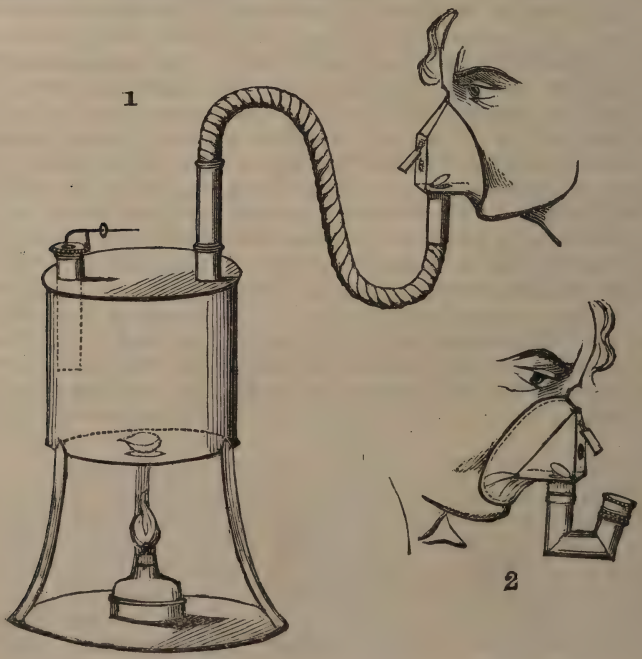
The most important of the additions to the mechanical means for inhalation, which followed the discovery of etherization, is the flexible face-piece, to include both the nostrils and mouth. Dr. Sibson introduced this, although Dr. Hawksley contrived a similar one about the same time. It is shewn in the engraving, which accompanies this paper, in the modified form in which I use it. The sides and margin, which form the flexible part, consist of thin sheet lead, lined with oiled silk, and covered with leather. The expiratory valve can be moved more or less to one side from the opening it covers, so as to admit unmedicated air, whenever the vapour feels too pungent. The advantages of a face-piece of this kind are, that it can be fitted to every variety of face; that the patient requires no instructions, having nothing to do but to continue breathing in his usual way, either by his mouth or nostrils, as he pleases; and that it imposes no labour on the respiratory muscles, for when applied to any suitable form of inhaler, it may be kept attached to the face for any length of time without fatigue. As I recommend the face-piece in every kind of inhalation (except where substances have to be drawn into the larynx in the form of powder, when a glass tube may be used), it has been described before treating of individual medicines, to which attention may now be directed.

I. INHALATION OF MEDICINES WITH THE AID OF HEAT.

A. IN THE DRY WAY. OPIUM, it is well known, is very extensively inhaled, in China and India, as an indulgence; but it has not been much used in this manner in the practice of medicine, so far as I am aware. I sought to ascertain the temperature at which the active ingredients of opium are given off, and whether the effects of the fumes are due to morphia, or to new products generated by the heat applied. For this purpose, I heated morphia and the meconate of this alkaloid in an oil bath, using a long narrow

test-tube, on the recommendation of Dr. Bence Jones. I find that neither pure morphia nor the meconate are volatile, unless the heat be raised till they begin to be decomposed. This occurs at about 400° Fahr., when they become brown, and a brown sublimate begins to be condensed in the interior of the tube. The sublimate obtained from morphia is slightly reddened by nitric acid, but is not altered by the perchloride of iron. The sublimate from the meconate gave the same results, except on one occasion, when some minute colourless crystals were sublimated from it, at a temperature of from 380° to 400°. These were rendered of a deep red by nitric acid, and were reddened also by the perchloride of iron. We may conclude, therefore, that the effects produced by the inhalation of opium are chiefly, if not altogether, due to the generation of new products by the heat applied.

For the inhalation of opium, the Chinese use a pipe of a peculiar construction, which they heat over a spirit lamp. The preparation which they use is the watery extract, and the quantity employed at one time is said to be a piece about the size of a pea; but whether the dose requires to be increased with the habit of using it, as happens when opium is taken into the stomach, I have not been able to learn. The Chinese opium-pipe is too complicated for general use by patients, and anything in the form of a pipe would be liable to misuse; as Europeans, with the exception of the Turks, use a pipe merely to draw the air into the mouth and puff it out again, instead of inhaling with it, as I believe is the practice in all eastern nations. I have therefore contrived an inhaler, which is adapted for a great number of other medicines as well as opium. (Fig. 1.)



1. Larger Inhaler. 2. Smaller Inhaler.

It is made chiefly of tin, and consists of a cylindrical chamber, between four and five inches in diameter, and three or four inches deep, under the centre of which a spirit lamp is placed. The bottom of the inhaler consists of a thin piece of talc, on which is placed a small capsule of Berlin-ware, for the purpose of holding the extract of opium. A porcelain funnel-holder, which is placed on the talc, keeps the capsule exactly over the flame of the lamp. The talc allows sufficient heat to be transmitted to the opium, without conducting it to the sides of the inhaler, and, consequently, the air which is inhaled is not unduly heated. The lid of the inhaler is moveable; it is provided with a delicately balanced valve for the admission of air, and is connected with the face-piece before mentioned, by means of an elastic tube of wide calibre, as shewn in the engraving.[1]

The extract of opium, in the form of a pill, is placed in the capsule without any addition, and the spirit-lamp is lighted beneath it with a very small flame, which may be increased if requisite. The patient begins to inhale immediately the lamp is lighted, and continues to do so as long as anything is given off. The moisture contained in the extract is first expelled by the heat and inhaled, then follow the active principles of the opium, accompanied, after a time, with some smoke, and nothing is left but a porous carbonized mass. The process, being conducted slowly, usually lasts about ten minutes. If the volatile products be too irritating at any time, and excite coughing, the spirit-lamp should be removed for a minute, the inhalation being continued, however, in the mean time. The patient learns very soon to accommodate the process to his tolerance of the vapour, the pungency of which is very slight.

At the Hospital for Consumption at Brompton, the physicians to which institution kindly invited me to assist in contriving and superintending the inhalation of medicines, a considerable number of patients have inhaled opium during the last twenty months,—some of them having inhaled every evening for several weeks in succession, and discontinued only on leaving the hospital. Three or four of the patients had emphysema with chronic bronchitis; but the majority had phthisis, with cavities in the lungs—cases, in which the cough was more than usually troublesome, being generally chosen. The cough was relieved by the inhalation in the greater number of cases, and many of the patients increased in weight, and improved considerably in general health. Other remedies were used at the same time, and contributed to the improvement, but it seemed to be in part due to the inhalation. It has caused constipation of the bowels in only two or three of the patients; I have, however, experienced that effect when I have inhaled it for experiment. The quantity of watery extract of opium inhaled at one time has generally been two grains; but, in a few cases, three grains have been used. Crude opium was used in one case, instead of the watery extract; but the fumes it gives off are more irritating to the bronchial membrane, than those from the latter agent.

Morphia is, in my opinion, the most suitable preparation of opium for inhalation; but I have not recommended it at the Brompton Hos-

[1] The Inhalers are made by Matthews, Portugal Street.

pital, on account of its expense. It has, however, been inhaled by one patient, in the dose of half a grain, and I have inhaled it in the same quantity. It is much easier and pleasanter to inhale than the extract of opium, the extractive matter of which supplies some smoke, which is probably quite inert. It is of service to mix the morphia with a little dry plaster of Paris, to give it more weight and bulk.

With respect to the doses just mentioned, it should here be remarked that a medicine, when inhaled, cannot be all absorbed, as usually happens when it is taken into the stomach, for only part of it reaches the lungs, whilst another part is expired again with the air which has occupied the nostrils or mouth, the larynx, trachea, and larger bronchi. I am inclined to believe that about one-half of what is inhaled is usually absorbed; for, on inhaling air charged with vapour of chloroform from a bladder or small balloon, I experienced as much effect from ten minims, when it was breathed backwards and forwards for a minute or two, as from twenty minims, when the air was only breathed once.

Extract of Stramonium has been inhaled in the Brompton Hospital, with more or less relief, by five or six patients affected with asthma. Four grains were used, in the same manner as opium. The spirituous extract of aconite was used also by one patient, in the quantity of a grain; and it is probable that other extracts might be employed with advantage, in the same manner.

Gum-Resins. The fumes given off by these medicines may be inhaled in the same way as opium; but, as these fumes are pungent when in large quantity, it is advisable to powder two or three grains of the gum-resin, and mix it with about ten times as much of some inert powder, as gypsum, before exposing it to heat in the capsule. Used in this way, ammoniacum gives off a very fragrant odour, and, though rather pungent, can be inhaled very well by most persons. With steam the gum-resins can be easily inhaled, as the quantity of vapour which they give off, at the temperature of boiling water, is small. In this way, however, the patient gets no great amount of the medicine; but probably enough to exert some local action.

b. With Vapour of Water. For the inhalation of medicines along with the vapour of water, I employ the above-described inhaler, using a somewhat larger earthenware capsule than for inhalation in the dry way. Into this capsule or dish, about half an ounce of water is put, together with the medicine to be inhaled. The water is heated by the spirit-lamp, sometimes till it boils gently, but generally to a point rather short of boiling. This quantity of water yields as much vapour as a patient can conveniently breathe in about half an hour; and a much greater amount of the medicine can generally be inhaled than if it were placed in a larger quantity of water. In the case of some substances, indeed, as iodine, oil of turpentine, and camphor, which are particularly adapted for inhalation in this manner, the medicine is all inhaled before the water is finished.

Iodine may be most conveniently inhaled, by adding a small quantity of a strong spirituous solution of it to half an ounce of water. Twelve minims of the iodine tincture of the *Dublin Pharmacopœia*, containing one grain of iodine, are a suitable dose. The advantage

of adding the iodine in the form of tincture is, that it becomes equally diffused through the water. As the patient inhales, the water becomes less and less deep in colour, and by the time that he has inhaled about three-fourths of the water, he has inhaled the whole of the Iodine; and the remaining water is colourless. On account of its irritating effects on the stomach, it would probably be advisable that iodine should be given by inhalation, in every case in which its exhibition is required. Allusion is here made only to iodine, and not to the iodide of potassium, which, not being volatile at the heat of boiling water, cannot be inhaled in this manner. I very much doubt whether phthisis be one of the diseases to be benefited by iodine. It was inhaled by eighteen patients at Brompton, in the summer of 1849, and the following autumn and winter; they generally commenced with half a grain, and it was increased, in one or two cases, to two grains; but the usual dose was a grain once a day. In two or three cases it was discontinued, as it seemed to increase the cough, and one or two of the patients complained of head-ache from its use. It was continued, however, for more than a month, in ten of the cases; and I was present on nearly every occasion, to see it inhaled. It may consequently be said to have had a fair trial; but no benefit could be observed to follow its use. It was not inhaled as above recommended, but from a Woulfe's bottle, over the interior of which its spirituous solution was diffused; no artificial heat nor vapour of water was employed; the inhalation was continued till the iodine had disappeared. There were consequently no extraneous circumstances to interfere with its action.

Oil of Turpentine has been inhaled in a few cases, by putting twenty drops of it, with about half an ounce of water, into the capsule; the spirit-lamp being placed underneath, as usual. The boiling point of oil of turpentine is much higher than that of water; but owing to the great density of its vapour, as compared with steam, it evaporates more quickly than water, as happens with iodine, and consequently it is all inhaled before the water is consumed. The cough has appeared to be relieved in the cases in which it was used. One was a case of hæmoptysis, which subsided under its use, as, however, it might have done without it.

Camphor can be conveniently inhaled by putting thirty or forty drops of the tincture into half an ounce of water. It is usually consumed as soon as the water with which it is mixed. It has appeared to relieve the cough, in a few cases in which it has been used.

Benzoic Acid can be inhaled with the vapour of water. If six grains be put into half an ounce of water, the patient will inhale about half of it, and should leave off before the water is quite dried up, to avoid the pungent fumes which would otherwise arise. For the next inhalation, some water and about three grains more of benzoic acid can be added to that which remained. I have not seen sufficient of its employment to speak of its effects.

Creasote may be best inhaled in the same manner. If not more than about four drops be put into the half ounce of water, all of it will be inhaled. I have generally given creasote, however, with the inhaler marked number 2 in the engraving. Several patients have inhaled it at the Brompton Hospital, generally using three or four drops twice a-day. The benefit from its use has not been very great, but might

probably have been greater, if it had been inhaled with vapour of water, which itself is serviceable.

II. INHALATION OF MEDICINES AT THE ORDINARY TEMPERATURE.

The smaller inhaler, shewn in the engraving, was contrived for the inhalation of chloroform in medical and obstetric cases. It is made of brass tube, rather less than an inch in diameter, and is lined with bibulous paper to absorb what is put in, and afterwards yield it up in the form of vapour as the patient inhales. It is adapted by a screw to a face-piece similar to that employed with the other inhaler. It is not my intention to speak of chloroform on the present occasion. Amongst the other medicines which have been inhaled with it, are hydrocyanic acid and conia; and it is adapted for the inhalation of almost any agent that does not require the application of heat.

Hydrocyanic Acid has been inhaled by several patients at the Brompton Hospital, but it has not seemed to produce any good effects which would not have resulted from its use by deglutition. The quantity inhaled was generally twice as much as one would give by the stomach, and it was somewhat diluted with water, to diminish the pungency of the vapour, and enable the nurse to measure the quantity more easily in the minim glass.

Conia, the volatile alkaloid of spotted hemlock, has been inhaled by several patients. Some of this active principle having been kindly given to me by Mr. Morson, I first tried small doses on myself, and found that a minim of it could be inhaled without inconvenience. This was the quantity usually administered, although two minims were inhaled in a few cases. Dizziness was caused by it in many instances, especially when the larger dose was employed, but this effect subsided in less than an hour. The cough was usually relieved by it, and in two or three cases of asthma, the breathing was also relieved. The conia was diluted with nine parts of spirit, both for convenience in giving the right dose, and in order that it might be better diffused over the paper in the inhaler, and offer a larger surface for evaporation.

The following experiment, performed in 1848, on the inhalation of conia, may not be uninteresting, as shewing that this is one of the agents which might be employed for the prevention of pain in operations.

A chaffinch was placed in a covered glass jar, holding 100 cubic inches, and one grain of conia was put in. The bird seemed unaffected for ten minutes, and the jar was opened with the intention of trying a larger dose; a minute afterwards, however, it fell on its side and lay, not relaxed, but like a stuffed bird, as its head did not droop. It moved its legs, now and then, by convulsive starts. It was insensible to pricking and pinching, although, from the appearance and motion of its eyes, it seemed to be conscious all the time. It recovered its sensibility in about two minutes, but was not able to stand for ten minutes. It afterwards appeared well.

In a guinea-pig, in which the inhalation was continued till a fatal effect was produced, violent convulsions occurred before death, and the heart remained irritable afterwards.

Ammonia has been inhaled with great relief in a few cases, in which more or less bronchitis, with difficulty of expectoration, existed.

The inhaler employed was similar to that described by Mr. Smee in the *Medical Gazette* for 1843, except that an elastic tube and face-piece were attached to it. It consists of a Woulfe's bottle with wide apertures, and a tube for the entrance of air, descending a certain way, but *not* dipping into the solution employed. The ammonia was given weaker than by Mr. Smee. Two ounces or so of cold water remained constantly in the bottle; and when it was about to be used, twenty minims of strong solution of ammonia were added, and the patient inhaled for half an hour, or as long as ammonia continued to be given off. The inhalation was repeated twice or three times a day.

It may be remarked, that either ammonia or hydrocyanic acid might be inhaled, along with vapour of water, in the opium-inhaler first described; so that a person provided with it might apply it in almost every kind of inhalation.

Chlorine has been inhaled by a few patients, in different stages of phthisis, but with no advantage, although it was continued by some of them for a few weeks. To obtain it, some chloride of lime was put into the Woulfe's bottle-inhaler, just mentioned, and moistened with a little water. When it was wished to increase the quantity of chlorine beyond the small amount spontaneously given off, the inspiratory valve of the face-piece was prevented from closing completely, and a little of the expired air being thus allowed to get into the bottle, the carbonic acid it contained acted on the lime, and caused chlorine to be liberated.

It will be observed, that the medicines mentioned above have all been recommended to be inhaled, either alone, or with the vapour of water: and, as a general rule, it is better for medicines to be inhaled singly; since, no two being equally volatile, they could not be inhaled, if combined, in the proportions in which they might be mixed. The method of administering medicines by inhalation also being yet as it were, in its infancy, the exhibition of one at a time is better adapted for the collection of correct observations respecting their effects.

54, Frith-street, Soho, January 2, 1851.

REMARKS ON CONTINUED FEVER, AND MORE ESPECIALLY ON THE CONDITION OF THE BRAIN IN FEVER.

By HUMPHRY SANDWITH, M.D., Physician to the Hull General Infirmary.

(*Read before the Hull Medical Society, Oct. 26th*, 1850.)

As Englishmen we must honestly admit, in spite of our proud recollections of what English observation has achieved from the days of Sydenham downwards, that the French have won imperishable laurels in the important field of Febrile Pathology. It is due, indeed, to the memory of Sir John Pringle to assert, that, even a hundred years ago, he caught a glimpse of the doctrine that, when fever proves fatal, it mostly or often does so by the production of certain specific organic lesions. This truth, though crudely stated, is embodied in the assertion, that "he examined ten patients who died of typhus, and came to the conclusion, that, when it proves fatal, it generally terminates

either in an actual mortification of some part, or in an abscess of the brain; but that the intestines are more particularly disposed to mortify."[1] This was in 1750. Ten years afterwards, Rœderer and Wagler, in Gottingen, state, as the result of their dissections in an epidemic typhus, that "they found intense inflammation of the alimentary canal; and that either gangrene and sphacelus occurred in the tract of the large intestines, or else that the mucous follicles of the *small* intestines were enlarged, with similar spots of gangrene or sphacelus."[2] In 1803, M. Prost opened the bodies of upwards of one hundred and fifty persons, who had died of *fièvre ataxique*, "without observing anything remarkable in the brain, but he always found inflammation of the mucous membrane of the intestines, with or without excoriation."[3] Following up these researches, Louis, Andral, Bretonneau, Broussais, Bouillaud, Petit, Serres, and others, have immensely increased our knowledge of fever by their separate contributions to its pathology. Louis was the first to appropriate the term *typhoid* fever to the morbid state which accompanies the lesion of Peyer's glands; an affection first distinctly pointed out by Bretonneau, under the name of *dothinenterite*. It is true that Petit and Serres, as well as Andral and Broussais, had previously described this enteric exanthem through all its stages, but had failed to mark its especial seat in the follicles. Andral objected to the application, by Louis, of the term *typhoid* to the fever accompanying this lesion of Peyer's glands. But recent observations by our contemporary, Dr. William Jenner, warrant the distinctive epithet of Louis, *at least for practical purposes*. For Dr. Jenner, as is well known, has discovered that *a rose-coloured rash* on the skin is characteristic of *typhoid* fever; while *mulberry-spots* are equally distinctive of *typhus*. His experience, fortified by two thousand cases, enables him to assert, that if by the eighth day of the disease the eruption presents the true *typhus*, or *mulberry* character, then, if death ensues, the follicular intestinal lesions will not be discovered. His conclusion is, that the *rose-coloured rash* is generally, though not invariably, associated with the follicular exanthem of *typhoid* fever; but that the *mulberry rash*, characteristic of *typhus* fever, is never associated with that peculiar enteric lesion. An American writer, Dr. Bartlett, is of the same opinion, and asserts "that there is as much difference between *typhus* and *typhoid* fever, as there is between measles and scarlatina."[4] The non-acquaintance of English observers, until of late years, with the follicular exanthem of *typhoid* fever, has led some French physicians, and especially M. Grisolle, to confine the disease to the continent, and to distinguish it from *typhus* fever, which they consider to be peculiar chiefly to England. In the article "Typhus", of the *Dictionnaire de Médecine*, M. Dalmas esteems *typhoid* and *typhus* to be "analogous", but not identical. It may be doubted, after all, whether the distinction can be maintained, except for practical purposes. Nor am I convinced, that *typhoid* and *typhus* are essentially distinct diseases. Both are forms of adynamic fever—mere varieties—exhibiting different phenomena

[1] Williams, Dr. Robert. Elements of Medicine, vol. i, p. 42.
[2] Ibidem. [3] Ibidem.
[4] Dunglison. Practice of Medicine, vol. ii, p. 494.

under different circumstances, the follicular abdominal lesion being generally present in France and America, whilst in England it is comparatively much rarer. "At certain times and places", says Dr. Watson (in other words, in certain epidemics), "the ulceration of the inner surface of the intestines is far less common than in others. It was comparatively rare in an epidemic, of which I witnessed some part in Edinburgh. Then I came to London; and for several years I never saw a body opened after death by continued fever, without finding ulcers in the bowels. More recently, however, and especially during the present epidemic (1838), I have looked for them carefully in many instances that have proved fatal in the Middlesex Hospital, and have discovered neither ulceration, nor any other apparent change in the follicles of the intestines".[1] As additional proof that typhoid and typhus fevers are simply varieties of the same essential disease, of which the *typhoid* form prevails chiefly on the continent and in America, and *typhus* chiefly, though by no means exclusively, in England, it has been observed that on the examination of those who have died of ship-fever, which is an adynamic petechial typhus, the follicular lesion is generally absent, *and yet exceptional cases of its presence now and then occur*. On the other hand, Dr. William Jenner himself admits, that, occasionally, though very rarely, in typhoid fever with the rose rash, the follicular lesion is wanting. Again, M. De Claubry has proved, in a prize essay on the *Identity of Typhus and Typhoid Fever*, to the satisfaction of MM. Chomel and Louis themselves, that the typhoid fever of M. Louis is the same as the typhus of armies, and equally contagious.[2]

Professor Rokitansky, of Vienna, has developed a still more novel view of the nature of the typhoid affection, or "typhus", as he calls it. His view is that it is a true dyscrasy, or cachexia, and that the pathological process is characterised by the deposition of a peculiar morbid product, which forthwith undergoes a distinct series of morbid changes. "The seat of this process is various, and depends upon the specific relation of the poison of typhus to certain organs. The tissues most subject to this deposition are *the mucous membranes, especially the space between the mucous and the muscular coat, and the mesenteric glands;* and in Austria, at least, where the observations were made, *the mucous membrane of the ileum* is most frequently affected; but it occurs also *in the bronchia and lungs*, and, although very rarely, *in the colon*. This typhus deposit, according to M. Vogel, usually appears as a more or less firm lardaceous mass, of a yellowish or whitish colour, which is deposited in greater or less abundance amongst the normal tissues, gradually softens, and, as the normal elements of the region become also involved in the process, forms ulcers, which either heal by cicatrization, or continue until the death of the patient. In many cases, however, death takes place before the commencement of the softening. The typhous matter, under the microscope, appears to consist of three elements; an amorphous semi-transparent stroma, very minute molecular granules, and larger corpuscles, which seem to be imperfect cells and cytoblasts. Histologically it cannot be distinguished from

[1] Watson's Lectures on the Practice of Physic, vol. ii, p. 689.
[2] Dunglison. Practice of Medicine, vol. ii, p. 493.

the deposits, that occur in scrophulosis and tuberculosis."[1] The local importance of this deposit cannot be questioned, as many cases terminate fatally from its effects,—ulceration, perforation of the intestine, etc.

CONDITION OF THE BRAIN IN FEVER. The microscope holds out to us a prospect of settling the much disputed point, whether or not the brain often suffers from inflammatory lesions in fever? The eye is, perhaps, competent to decide on the evidences of inflammation in the membranes; but it often fails in deciding the question, as it concerns the substance of the brain. For it is not always easy, even to careful observers, to distinguish between the hyperæmic condition which is the result of inflammation, and that which may be termed *cadaveric*. The conclusions of Dr. Hughes Bennett, as to the results of simple inflammation of the brain, from careful observation by the microscope, seem, in many points, applicable to the case of inflamed cerebrum in fever. They are as follow:—

1. "That two kinds of cerebral and spinal softening exist, an inflammatory and a non-inflammatory, which may always be distinguished from each other by the microscope.

2. "That inflammatory softening is characterised by the presence of exudation corpuscles and granules, whilst in non-inflammatory softening these bodies are never found.

3. "That the nature of inflammatory softening consists in the formation and development of nucleated cells in exuded blood-plasma; whilst the nature of non-inflammatory softening consists in the mechanical destruction or maceration of the nervous tissue in serum, or is the result of putrefaction.

4. "That non-inflammatory softening, unaccompanied by hæmorhage, is usually *post-mortem*, and causes no symptoms; whilst uncomplicated inflammatory softening always causes marked symptoms, which, however, vary according to the seat of the lesion.

5. "That the inflammatory and non-inflammatory softenings have frequently been confounded together by morbid anatomists, it being impossible to distinguish one from the other with any certainty by the naked eye.

6. "That inflammation in the nervous centres has, in several instances, been demonstrated by means of the microscope, after it has escaped the search of good morbid anatomists, and been indicated by most unequivocal symptoms.

7. "That every different coloured softening has, at various times, been found to be connected with inflammation; but that yellow and white softenings are most frequently non-inflammatory, whilst the fawn-coloured softening is non-inflammatory.

8. "That red softenings usually depend on congestion, or the direct extravasation of blood; yellow softenings on the imbibition of the colouring matter of the blood; fawn and grey-coloured softenings on the presence of grey exudation corpuscles; and white softenings, in the great majority of cases, are *post-mortem*, and the result of maceration in the serum."[2]

[1] DUNGLISON. Practice of Medicine, vol. ii, p. 494.

[2] SOLLY on the Structure, Physiology, and Diseases of the Human Brain. Second Edition, p. 386; quoted from *Edinburgh Med. and Surg. Journ.*, vol. lx, p. 398.

Perhaps no subject has more puzzled medical observers than the true condition of the brain and nervous centres in continued fevers; and in no case has speculative error produced more extensive practical mischief. Genuine encephalitis may be mistaken for continued fever with intercurrent inflammation of the brain; and continued fever so complicated may be treated for pure encephalitis, with its symptomatic febrile excitement. Close observation and an acute judgment are required for discriminating those cases of fever in which such inflammation occurs, and for directing the appropriate treatment. Moreover, during the present prevailing constitution of the seasons, we often witness a condition of the brain in fever, which merely simulates inflammatory congestion, and depends either on the want of a normal *vis a tergo* in the circulation, or on an impaired function of nutrition favouring a species of *ramollissement* of the tissues. This kind of softening is not owing to the effused serosity from distension of the capillaries, but is always in proportion to the fluidity of the blood, and the tendency of that fluid to run into putrefaction. "There is a modification of nutrition", says Dr. Carswell, "which is accompanied by softening of *all* the tissues (those of the brain of course included), and which seems to depend on a morbid condition of the blood. Such is the case in the worst forms of typhoid fevers, small-pox, scarlatina, measles, etc., and when certain poisons have been introduced into the circulation."[1]

The inquiry, therefore, *what is the condition of the brain in fever?* is fraught with the deepest interest. Dr. Copland states a great and golden truth, when he says: "*Predominant cerebral affection* less frequently amounts to actual disease, or passes into disorganization, in fevers, than has been very generally supposed; the disorder most commonly existing in this quarter, *in low fevers especially*, being more functional than structural; depending more upon the state of organic nervous influence in the organ, than upon inflammatory or other lesions. The effusions and congestions observed in fatal cases, are probably in great measure *post-mortem* changes; and, even granting their existence during life, they are often insufficient to account for the symptoms referable to this part."[2] I propose first, to confirm this great truth by a reference to the best authorities; and secondly, to guard the doctrine from abuse, by pointing out those deviations from a general rule, which have ever and anon occurred to the most trustworthy observers.

I. CEREBRAL AFFECTION IN FEVERS IS MORE COMMONLY FUNCTIONAL THAN STRUCTURAL.

M. Louis does not seem inclined to believe that either the general softness or hardness of the substance of the brain, occasionally observed in fever, ought to be considered as the results of inflammation, because the symptoms during life do not bear an appreciable relation to these appearances. He also affirms, that having examined with much attention the cerebral membranes in more than five hundred cases, he has in no instance seen adhesions between the arachnoid and pia mater, either at the surface or in the ventricles of the brain. Moreover, his exceptional cases to perfect integrity of cerebral structure, though in-

[1] Carswell. Pathological Anatomy. Article, "Softening."
[2] Dictionary of Practical Medicine, p. 920.

dicating an occasional approximation to inflammation, are, for the most part, much too slight to warrant Dr. Clutterbuck's theory, that fever results from inflammation of the substance of the brain. Thus he states, that, "besides a case in which the inside of the dura mater presented a thin pseudo-membrane, in *four* there was a little fluid between the dura mater and arachnoid; in *more than one half* the subarachnoid cellular tissue was infiltrated with serosity, and in *one half* the pia mater was injected with blood. In *three-sevenths* the cortical substance was redder than natural; in *six-sevenths* the medullary matter was injected, these latter appearances being most striking when death took place at an early stage; in *six* cases the density of the brain was slightly increased; in *five* it was diminished."[1] Andral, in like manner affirms, that no truth is better demonstrated in medicine than that every nervous derangement may exist in fever, and yet no appreciable alteration of the brain or its membranes be found after death. "In a great number of cases", he says, "the substance, so far from being injected, appeared remarkably pale, and this paleness frequently coincided with an equal want of colour in the membrane." Chomel's observations are strongly corroborative of those of Louis and Andral. He gives the following statement in respect to thirty-eight fatal cases, in which the brain was carefully and minutely inspected by him. "In fifteen out of the thirty-eight, no morbid appearance at all was perceptible: in twelve there was some serous fluid, from a tea-spoonful to a table-spoonful, in the ventricles: in seven there was what he calls *œdema of the meninges*, effusion, that is, in the meshes of the pia mater: in six, general but slight diminution of consistence: in two, some alteration of density: and in five, a speckled appearance of the cerebral substance."[2] Dr. Watson's testimony is confirmatory of the same general view. "Not only", says he, "do we fail to discover, in many instances, any traces of inflammation, upon inspecting the dead brain, but we find that, during the life of the patient, measures which would be likely to aggravate any inflammatory mischief—strong stimulants for example, wine or brandy—do actually and obviously, in cases innumerable, relieve the comatose symptoms, and benefit the patient. The inference seems unavoidable, that the coma, in such cases, has some other cause than the mechanical pressure which arises sometimes from the effusion of fluid upon the surface of the brain, or within its ventricles; and that other cause is supplied by *the poisoned blood*."[3]

We have the light of analogy thrown on this view of the subject by what occurs in scarlet fever in its malignant forms. Hence Dr. Graves, in describing the forms of scarlatina, sensibly remarks:—"In this form of the disease, where the pulse, without becoming strong, *at once became extremely rapid*, bore venesection badly, and required great caution even in the application of leeches; the nervous symptoms only appeared accelerated by the system of depletion, although the heat of the skin suggested its employment. The derangement of the brain and nerves in this form depended on something more than the violence of the circulation, and originated in something altogether different from mere cerebral inflammation or congestion. What that something was

[1] Cyclopædia of Practical Medicine, vol. ii, p. 178.
[2] As quoted by Dr. Watson in his Lectures, vol. ii, p. 683.
[3] Watson. Lectures on the Principles and Practice of Medicine, vol. ii, p. 683.

I cannot even conjecture; but it was probably the result of *an intense poisoning of the system by the animal miasma of the scarlet fever.*"[1] Cholera, in its worst forms, seems to point to a similar explanation of sudden collapse and death. And we may fairly conjecture, that *some* of those sudden deaths in fever, which occasionally take us by surprise, may be thus accounted for. Dr. Alison's remarks on *post-mortem* appearances within the cranium after idiopathic fever, go very much to the same point as those of the authorities already quoted. He tells us that they are confined, in by far the greater number of cases, to increase of the natural serous exhalation on the different surfaces, particularly in the ventricles and beneath the arachnoid coat, that it very seldom amounts to an ounce, and that it is very generally much less than in fatal cases of idiopathic inflammation within the cranium, whether acute or chronic. He makes equally light of the turgescence of the blood-vessels, and thinks that even depositions of lymph are often due to previous disease rather than to fever.[2]

II. FEVER IS SOMETIMES ASSOCIATED WITH CEREBRAL INFLAMMATION.

Having thus adduced the authority of a few of the highest names in French and English medicine as to the fact of the general absence, in fever, of unequivocal traces of cerebral inflammation, it becomes my duty equally to guard that doctrine against the misconception *that fever is never associated with cerebral inflammation.* I shall, therefore, marshal a sufficient amount of evidence, on the other side, to qualify the too sweeping conclusion which might be drawn from a *primâ facie* view of the subject. And it will at once appear, that not only do stray cases of cerebral inflammation occasionally break the uniformity of a non-inflammatory series; but also that epidemics are wont, in certain seasons, to arise with types of sthenic action, and with a decided bias to cerebral lesions.

a. Stray Cases of Cerebral Inflammation occur in Fever. Dr. Mackintosh has left on record some particulars of an epidemic fever in Edinburgh in 1827. The disease was mild, especially in the beginning; for, out of the first hundred and forty cases, there was only one death. Afterwards the deaths were in the proportion of one in thirty-seven. Amongst other results of the disease, as exhibited in various organs by dissection, he tells us that "in two cases, there was well-marked arachnitis, namely, by extensive effusion of coagulable lymph, which was deposited between the arachnoid and dura mater. In both there was great vascular turgescence; some effusion into the ventricles; and in one of these there was white ramollissement in the centre of the brain".[3] Dr. Duncan Junr.'s *Clinical Reports* for 1818, in like manner furnish us, from the pen of Dr. Craigie, with two dissections of cases of fever with cerebral lesion, in one of which there was effusion in the left lateral ventricle to the amount of from one to two ounces of transparent colourless fluid, with the rest of the organs sound; and in the other there was a similar effusion, but its amount is not specified.[4] Dr. Roupell, in his *Treatise on Typhus Fever,* mentions a

case of effusion into the head, indicated by opening of the sutures. The youth, aegd. 19, recovered, and the sutures closed. In another, "lymph and serum were copiously effused into the ventricles, and a layer of lymph, fully a line in thickness, was found on the surface of the hemispheres. The other viscera were healthy." In another "there was great vascularity of the pia mater, especially at the base of the brain. The arachnoid membrane was slightly opaque, and there was a bloody fluid effused into the theca of the spine". And, in another, "the ventricles of the brain contained serous effusion; and a large quantity of bloody fluid filled the spinal sheath".[1] In one of Andral's cases of fever, with ataxic symptoms, and alternations of delirium with perfect intelligence, accompanied with hydrophobia and convulsions, "the cerebral sinuses were filled with blood, the cerebral substance of ordinary consistence, marked with a considerable quantity of red points, and about a spoonful of limpid serum in each lateral ventricle".[2]

b. Epidemics occasionally arise with a decided bias to Cerebral Inflammation. In the Bristol epidemic of 1820, as reported by Dr. Pritchard, he refers to cases of cephalic fever, and says that, when the symptoms of severe disease were not subdued by active treatment, "it was almost uniformly proved by examination after death, that the brain had suffered irreparable injury."[3] In the London epidemic reported by Dr. Tweedie, it would also seem that head-affections were predominant. For he tells us, that "of 54 cases examined at the London Fever Hospital, 37 exhibited evident traces of previous inflammation of the brain."[4] Dr. Cheyne's report of the Hardwick Fever Hospital in 1816-17, presents us with seven examples of cerebral lesion of the most decisive character:—for in one there were six ounces of fluid in the ventricles of the brain; in a second, five ounces of fluid in the ventricles; in a third, the minute vessels of the cortical substance of the brain were turgid, imparting to it a very red colour; in a fourth, the tunica arachnoidea was much thickened, with effusion betwixt it and the pia mater, and several ounces of fluid in the ventricles; in a fifth, the vessels of the brain were turgid, and there was one ounce of fluid in the ventricles; in a sixth, there was serous effusion under the arachnoid membrane, vascularity of the pia mater considerably increased, brain firm, a little fluid in the ventricles, and the velum interpositum thickened; and in the seventh, there was increased vascularity of the pia mater, with several red points on its surface; the texture of the brain very firm, and about ʒiij of serum in the ventricles.[5] Dr. Cheyne's report of the same Fever Hospital for 1817-18, yields ten examples of cerebral lesion equally decisive. I need not specify all: but in one the pia mater was highly inflamed, and the ventricle contained between three and four ounces of fluid. In another there was a layer of effused blood in different situations under the pia mater of both hemispheres. In another the same extravasation of blood was seen, and the arachnoid membrane between the convolutions of the brain was much thickened and opaque, and contained under it a gelatinous substance. In an-

other the membranes were thicker, firmer, and more opaque than natural, and a small quantity of blood was effused into the ventricles, the sides of which were very vascular. In another, along with signs of vascular engorgement of the membranes as well as substance of the brain, the ventricles were filled with serum. But I will not multiply details.[1] These statements by Dr. Cheyne are followed by a tabular view of the dissections in the latter of these epidemic fevers, from the pen of Mr. Crawford, from which it appears, that while there were only twenty-three examples of serious lesions in the abdomen, and twenty-two in the chest, there were thirty-seven in the head.[2] In many of the last, too, it is particularly noticed that all the other organs were free from lesion. It is impossible to compare these dissections with those reported by Andral without being struck with the fact, that cerebral lesions were, in the great French pathologist's experience, infinitely rarer and much less severe than those in Dr. Cheyne's, while the former records far more numerous and formidable abdominal lesions. It is most evident, therefore, that epidemics vary much as to the predominance of the lesion of one set of organs over that of another.

My next and final proof of this fact will be found in the description of the fever which prevailed in Scotland in 1843. Dr. Cormack[3] has minutely described the disease as it prevailed in Edinburgh; and Dr. J. Arrott[4] has given a short but good account of it as it occurred in Dundee. The same epidemic has also been described by Dr. Alison, Dr. Wardell, and others. Black vomiting was common, and the bile was generally very viscid. The appearances after death corresponded remarkably with those observed by the French Commission in the yellow fever of Gibraltar in 1828, particularly as regarded the condition of the liver, which M. Louis considers to be the anatomical character of yellow fever. Dr. Cormack has given a complete account of the Natural History and Pathology of the Edinburgh epidemic, and has elaborately compared it with other fevers.

Bearing in mind these exceptional inflammatory lesions of the brain, let us revert to the result of the voluminous post-mortem researches of the French pathologists,—namely, that in typhoid fever, *with the rose-coloured rash on the skin and the follicular exanthem in the bowels*, actual cerebral lesion is a most rare occurrence. Although we may have the most marked head-symptoms, our minds may in such cases be very much at ease respecting the state of the brain, and our efforts may be employed otherwise than in the worse than utopian effort to quell a simulated arachnitis. For it has been laid down as a principle, that "in this disease there is not a nervous symptom which may not manifest itself without any appreciable alteration in the brain and its dependencies; and that when anatomical lesions of the nervous centres are met with, they are so slight and inconstant as not to permit any rational consequence to be deduced from them." Andral's remark on this subject is extremely important and instructive. "May

[4] Arrott, Dr. J. Edinburgh Monthly Journal for 1844, p. 256; from *Scottish and North of England Medical Gazette.*

we refer", says he, " the nervous disturbances in bad fevers to the state of the small intestine, and particularly to dothinenterite? Certainly we may in a great number of cases, but not in all. In several of these cases, where, in order to account for the very severe symptoms, nothing is found but some follicular patches swollen or slightly ulcerated, there is some ground for hesitating to refer such great disturbance to such slight lesions; there is reason for thinking that behind these visible lesions, and before their appearance, there existed in the previous state of the patient some serious derangement, without which such alarming symptoms would not have been produced. No; the intestinal affection is not the entire cause in all such cases; and in order to account for every thing which coincides with it, or appears after it, it becomes necessary to introduce other elements, which pathological anatomy has not yet discovered by means of the scalpel. Here then, as in numberless other cases, that which we perceive is but a part of that which exists." He then refers first to those cases, in which the same nervous symptoms existed with *lesions of other organs*, but without any intestinal lesion appreciable by anatomy; and secondly to those uncommon, but yet real cases, in which, *in the absence of any organic lesion appreciable after death*, the same nervous symptoms were still present.[1]

Andral goes on to insist, that " these fevers never become severe except in consequence of a disturbance, which supervenes in the innervation and hematosis." Bouillaud and Chaufford confirm this view, " by establishing the reality of the alterations, which, on the one hand the blood, and on the other hand the nervous centres, undergo in a great number of fevers." It would seem, alike from the observations of Andral, Raciborski, and Simon, that the quantity of fibrin in the blood is certainly decreased, except on the supervention of inflammatory symptoms, when it increases. This diminution of fibrin Andral ascribes to a true poisoning of the blood. The corpuscles, as repeatedly examined by M. Donné under the microscope, did not, in the most marked forms of fever, exhibit any difference from those of healthy blood, although on the average less in amount. It also appears, that a decided decrease of the urea below the healthy average is a characteristic of the urine in typhus. Andral further shews, that " other organs also, though less frequently than the digestive tube, may become the occasion of this profound disturbance of innervation and hematosis"; and he instances phlebitis, pneumonia, erysipelas, variola, synovitis, and other diseases, as often producing it. He further refers to the poisoning of the blood by miasms, virus, and matters in a state of putrefaction, as a fruitful source of the disturbances and lesions in fever. The truth seems to be, that though various poisonous matters introduced into the circulation may depress the system, and predispose it for the full effect of a more specific poison, yet, except in those simulations of typhus fever supervening on other diseases, the miasm of typhus or typhoid fever is a *sine quâ non* to the production of these fevers. Assuming this fact, then, after the period of its latency in the blood has passed, the *primary* operation of the specific poison is on the great nervous centres, and on the organs and systems dependent on them, and this consti-

[1] ANDRAL'S Clinique Médicale, translated by Dr. Spillan, vol. ii, p. 628.

tutes the febrile explosion. But its *secondary* operation, after an indefinite period, is on certain organs or tissues, in which are produced local lesions or alterations of structure. The mucous membrane of some portion of the digestive tube, or Peyer's glands, is the most common seat of such injury; next, but far less frequently, the brain or its membranes; and, perhaps still less frequently, the parenchyma or bronchial membrane of the lungs. Such is the ordinary course of the malady; although it also appears probable from Andral's observation quoted above, that adynamic or ataxic febrile phenomena, simulating typhus, may also stand in the relation of effect to various other organic lesions and constitutional maladies. The law that fever precedes *the secondary specific lesions* from the morbid poison of typhus or typhoid fever is consonant with the laws of other morbid poisons, as those of small-pox, scarlet-fever, intermittent fever, etc.[1] Chomel had an opportunity of examining a patient, who died on the seventh day of typhoid fever, and he found even then the follicles of the mucous membrane of the intestinal tube enlarged.

Practical Remarks. Coupling the knowledge we have acquired from the French pathologists, respecting the prevalence of follicular lesion of the small intestines in typhoid fever on the continent, with what we know of its occasional occurrence in England, we shall be prepared for a rigid analysis of the cerebral symptoms in each case, with a view to ascertain whether these are the sympathetic consequences of enteric irritation, or the result of positive organic disease of the nervous centres. Nor must we lose sight of the fact, that febrile irritation has often the power to develope constitutional peculiarities of the nervous system, independently of any ascertained local organic lesion. Andral has recorded several cases of this kind. Thus in one, in which "no organic lesion was detected in any part of the body", there had been febrile delirium, and "from time to time the face and extremities were agitated by convulsive movements". On this case Andral pointedly remarks: "Can it be said that the disease existed nowhere, or, if some will have it so, that it existed everywhere? We shall not reason so; we shall place the seat of the evil where the symptoms pointed it out, namely, *in the brain:* but this fact is to be added to several others, which prove the insufficiency of our present means of investigation to discover, in the dead brain, the traces of the disease seated in it."[2] In another case, in which, towards the close of the disease, there supervened symptoms of tetanus, but in which the scalpel traced marks of enteric disease chiefly, Andral's remark is the following:—"If the tetanus was, in this individual, the result of irritation, transmitted sympathetically from the stomach to the spinal cord, there must be admitted to exist in this person a special predisposition, in virtue of which tetanus would have equally declared itself, no matter what organ had become the seat of irritation". Another form of cerebral irritation, which, however much it

[1] These *secondary specific lesions* are to be distinguished from those produced by *epidemic influence*, an influence which, as Dr. C. W. Bell justly remarks, gives to fevers "a pseudo-specific character, by superimposing upon them the peculiar derangement of function, which it is its province to produce." *Trans. of Prov. Med. Assoc.*, vol. xvii, p. 28.

[2] Andral's Clinique Médicale, translated by Dr. Spillan, vol. ii, p. 701.

may simulate phrenitis, implies a condition of the brain altogether removed from that of inflammation, is the result of depressing mental causes. A case of this kind occurs to my recollection, which was a most instructive example of the depressing power of intense mental agony, want of sleep, exhaustion from fatigue both of body and mind, and frequent fasting and irregularities in diet. Delirium, with fever, set in very early, and with it very soon the mulberry rash and petechiæ of malignant typhus. I had not shed a drop of blood by leech, or by lancet, and the antiphlogistic plan was soon exchanged for wine and stimulants; but collapse and death rapidly ensued. If again we find profound disturbance of the innervation combined with the rose-coloured rash, or, in its absence, with local tenderness on pressure over the ileum, our attention will be withdrawn from too exclusive an examination of the brain to the more pressing claims of the abdominal mischief for prompt remedial measures.

We have further to study the prevailing character of epidemic diseases, both as it regards their evident bias to affect one class of organs rather than another, and also as they may assume a low and typhoid, or a high-toned and inflammatory bearing. We must recollect also, that even the same epidemic will undergo a change in its character from the modifying influence of the seasons. "This, however, I am certain of", said the illustrious Sydenham, "from numerous careful observations, that the same method which cures in the middle of the year may possibly prove destructive at the conclusion of it". This observation I have myself verified at St. Bartholomew's Hospital. I have seen cases, with a small and depressed pulse, demanding wine to sustain the heart, and simultaneous local cuppings to free an engorged lung, at one period of the year; and other cases in the same epidemic at another season, requiring the withdrawal of the wine, and even the cautious use of the lancet, owing to their assumption of the inflammatory type, with a sharp and resisting pulse. And here I may be allowed to state my decided conviction, that a great change has lately, and especially during the choleraic constitution of the atmosphere, come over the nature of fever, and, in a less degree, over inflammatory diseases in general. This is no new thing. Fifty years ago puerperal fever, according to the united testimony of all the best writers of that period, would not bear bleeding or active purgation. Then followed a change in the seasons, which, according to the experience of Dr. Gordon of Aberdeen, Mr. Hey of Leeds, Dr. Armstrong of Sunderland, Dr. Campbell of Edinburgh, and others, demanded the most heroic depletory measures. I myself witnessed, and put on record, two epidemic maladies, typhus[1] and scarlet fever;[2] the former in 1819, and the latter in 1832; both of which required active depletion, both general and local. Since that period we have witnessed the recurrence of a depressing constitution of the atmosphere, which absolutely forbids all active lowering measures. On the contrary, so weakened are the vital powers, more especially in fever, that if we use the lancet we almost certainly destroy the patient; while leeches themselves sometimes render recovery difficult, or impossible. In short, a conservative treatment, consisting of the judicious combination of quinine, cordial

[1] History of the Bridlington Epidemic Fever in 1818 and 1819.
[2] Edinburgh Med. and Surg. Journal, October 1, 1833.

diaphoretics, diluted wines, and good broths, commenced very early in the course of the disease, promises more success than any other, and seems to sustain the function of nutrition, as well as to obviate those local congestions of the brain, and other organs, which appear to steal on our patients, from the loss of the *vis a tergo* in the heart and arteries. Sydenham, also, bids us attend to the type of contemporary diseases; adding, that the character of a fever "may often be sufficiently known by carefully attending to other diseases". Nor need I remind my readers how much, in ordinary seasons at least, a man's condition, situation, and circumstances, will often modify the complexion of a fever. "A well-fed, and previously healthy soldier, who has no cares, will in general have a high-toned fever; whereas a poor, ill-fed, and badly-clothed, labouring man, worn out by cares and anxieties, and living in an ill-ventilated and filthy apartment, will be affected with one of an opposite character."

In other adynamic and malignant forms of fever, we can undertand with Dr. Watson how the stupor is occasioned by the poisoned blood, and not by effusion in the brain, and we cannot, therefore, hesitate, in such cases, to administer cordials. In these adynamic forms of fever, Dr. Copland strongly recommends the chlorate of potassa; and Dr. Watson prescribes a solution of it in water, in the proportion of a drachm to a pint, as a drink. He states, that under the use of a pint, or a pint and a half of this solution daily, he has noticed, in many instances, a speedy improvement of the tongue; which, from being furred or brown and dry, has become cleaner or moist. At the same time, bearing in mind the depressing influences, with which our patients have to struggle, we give stimulants at the proper time, and with a bold hand. The knowledge, again, that the fibrin of the blood is diminished in typhus fever, and that the blood is doubly poisoned by an excess of urea, in addition to the specific miasm, will confirm us in the necessity of sustaining the vital powers, and of avoiding, as much as possible, all lowering agencies. Now and then, indeed, we meet with cases, in which life is so completely overwhelmed by the depressing miasm, as to hold all our efforts at defiance. For sporadic cases occasionally arise, of so unusually malignant a character as to defy all the resources of medicine. Thus, a few years ago, I was called to a family in Holderness, plunged into great distress from the sudden invasion of the farmer and his wife by what seemed to be a typhus poison; which proved fatal to them both within two days. The wife first fell ill, and was moribund when I saw her, with both her lower extremities cold and livid as high as the knees. Her husband had then, also, been seized a few hours, and was almost pulseless, with petechiæ in various parts of the body, insatiable thirst, parched tongue, and other febrile phenomena. There were neither the symptoms of cholera, nor those of poisoning, nor could they be traced to deleterious vegetable or animal food. Every attempt to sustain the sinking powers, in both these cases, proved wholly nugatory.

Instructed, however, by another class of important facts, we shall not blindly take for granted the absence of cerebral engorgement or arachnitis; but, admonished by the proved occurrence both of stray cases of cerebral lesion in epidemics characterized mainly by disturbance in other organs, as well as by the occasional predominance of brain affection in certain epidemics, we shall be on the look out for the possible

occurrence of such lesion, and give every case of equivocal aspect the benefit of a most rigid analysis from time to time. M. Rostan's conjecture too is worth considering, who suggests the possibility that inflammation of the brain and its envelopes may be induced by a special cause, as by animal matters in a state of putrefaction. We must note the tone and character both of the epidemic we have to deal with, and of contemporary diseases. We must bear in mind the importance of an early and anticipatory treatment, should cerebral lesion be actually pending. It is remarked by Dr. Graves, in reference to a case of intensely violent maculated fever, which, on account of head symptoms, had been leeched early, and the whole scalp blistered on the *fifth* day, and blistered again as well as the nape on the *eighth* day, that "*on the ninth day* the cerebral symptoms, *which we had been endeavouring to anticipate,* came on, but probably our treatment prevented them from being fatal; for when they appeared, the application of tartar emetic ointment induced a purulent discharge from the whole surface of the twice-blistered scalp, in the course of a few hours, and three grains of tartar emetic, given in divided doses that day, procured a complete cessation of the symptoms, after"—mark, after—"*the pupils had been dilated, and one fit of slight paralysis of the mouth and tongue had taken place.*"[1] It would be foreign to my purpose, and superfluous, to sketch all the symptoms of menaced cerebral lesion; I may notice, however, one on which Dr. Graves lays great stress. "On the morning of the eighth day", he says, in reference to a certain case, "we observed that every now and then he *respired irregularly,* as if repeatedly and gently sighing,—a variety of respiration often indicating a disturbance of the nervous system, and which I have repeatedly observed as a precursor of cerebral excitement, and to which, consequently, I have been in the habit of drawing the attention of my pupils, under the name of *cerebral respiration.*"[2] A most interesting case of the sudden supervention of the cerebral inflammation occurred to my observation in the Infirmary about three years ago, in the person of a sailor, who had gone on favourably up to that time. I had not seen him on the day when he was attacked with head symptoms. I was told, when I visited him the following morning, that on the day before, towards evening, he had become suddenly maniacal, and I found him manacled and strapped down to the bed. He had a sharp, rapid, and resisting pulse, a flushed countenance, a flashing eye with contracted pupil,—all the symptoms, in short, of arachnitis. I immediately took from his arm twelve ounces of blood, which was sizy, and put him under the full influence of tartar emetic. The bad symptoms were at once arrested, and he was convalescent in a few days. But the real difficulty lies, after all, in discriminating between the symptoms of merely sympathetic and actually organic disturbance of the innervation. No one can rise from the perusal of Andral, without a deeper impression on his mind of this important practical truth.

Postscript. Since the above remarks were written, the following interesting case of fever has occurred in my own family; and though not of a typhoid, but of a *remittent* type, its affinities to the subject of the previous inquiry are sufficiently obvious to warrant its insertion

[1] Graves. Clinical Medicine, p. 100. [2] Ibid. p. 88.

here. The case was so severe as fairly to justify the epithet of *malignant* remittent fever.

Case. Henry Sandwith, æt. 23, well-built and muscular, but having an irritable brain from night-work in study at an early age, in a large public school, has lately been again working hard, and encroaching upon the hours of sleep, in preparing for his degree at Cambridge. He has suffered from great and depressing anxiety on the subject.

Dec. 5, 1850. The attack of fever commenced to-day with constant shivering and aching in the joints. He took two grains of calomel and a black draught on his own responsibility. Unfortunately he had a small wine-party at his rooms this evening, but drank only two glasses of wine. The excitement of the evening was followed by a most restless night, crowded with strange and multitudinous dreams.

Dec. 6. He was still worse, and unable to look at a book. Diaphoretic medicines were given him, but they failed to act on the skin; the pulse that evening rose as high as 130.

Every night, from Dec. 5th to the 9th, his sleep was disturbed, unrefreshing, and filled with dreams. There was loss of appetite, with a white and parched tongue. He took a small basin of mutton broth each day.

Dec. 9. Wrote home, that he was a good deal prostrated, and could not read or do anything, but lay wrapped up on the sofa. The shiverings had much declined, but fever continued. Tea and toast turned the stomach immediately; broth alone remained. The tongue, to his own sense, was as parched and the taste as metallic as possible. He had felt unequal to write home on the 8th, though deeply sensible he ought to do so.

Dec. 10. Returned home to Hull by railway from Cambridge, a distance of 160 miles. He almost fainted on his journey. A fellow-passenger gave him a little brandy; he also ate an orange. That night he was restless, feverish, and his bowels were a little disturbed.

Dec. 11. Complained of a slight pain on the left side of the abdomen, near the sigmoid flexure of the colon, which was not, however, increased on pressure. The abdomen generally was soft, and gave no indication of pain on pressure anywhere. There was no distension.

Dec. 12. Had hæmorrhage from the bowels to the amount of about ten ounces at 2 o'clock P.M. He had been purged thrice in the night, the products of which an ill-informed nurse had removed. There is reason to fear that blood had been evacuated. A large blister was applied over the abdomen; and half-drachm doses of spirits of turpentine and castor oil were promptly given every third hour. There was hæmorrhage twice more, but not to any amount, not more than three or four ounces in all. This was succeeded by several copious, watery, pale-yellow stools, with tenesmus. The simple aromatic chalk julep, to the extent of thirty grains, with a grain of opium and Venice soap, as a suppository, quieted the commotion. That evening his pulse dropped considerably, the skin for the first time gave way, and he had free perspiration, and slept well the whole night.

Dec. 13. Tongue still furred and white, though breaking up a little; thirst extreme; all the symptoms in short marking great erethism in the gastro-intestinal mucous membrane. There was now a marked exacerbation of fever twice daily, with slight chilliness, suc-

ceeding fever, and eventual perspiration. Towards evening this day he got out of bed under feverish excitement, though he was not maniacal. He left his bed under an impression that he should die the next day, and wished once more to walk across the room. He passed a sleepless night, with great heat and thirst, and laboured under deep and settled melancholy.

Dec. 15. There was hæmorrhage from the bowels at 4 o'clock A.M. to upwards of a pint; and again at 11 A.M. to nearly the same amount. Great faintness came on after the first loss, requiring a little brandy and sal volatile in water. We immediately gave him three grains of acetate of lead with one-sixth of a grain of opium, followed by three grains more of the lead an hour afterwards, and then successively two-grain doses every second hour, until a scruple had been taken. The intervals were then prolonged to four hours during the consumption of ten grains more, making in all thirty grains, when, as all hæmorrhage had ceased, the medicine was suspended. After each of the hæmorrhages, we also threw up the most powerful astringent injections. Sixteen grains of pure tannin dissolved in twelve ounces of warm water, were administered as a cold enema twice; then a solution of matico; and lastly two injections with a drachm of tincture of sesquichloride of iron in ten ounces of water. By these measures in combination the hæmorrhage was happily arrested.

To meet the tendency to collapse, a table-spoonful of old port wine in gruel, alternated with beef tea, every hour and a half, was steadily administered, also a little hock and water to quench the thirst. Two grains of sulphate of quinine, with five minims of elixir of vitriol, dissolved in water, and a drachm of Huxham's tincture of bark, every fourth hour, were substituted for the acetate of lead.

Dec. 18. There having been no evacuation of any kind since the 15th, the bowels were relieved by two-drachm doses of castor-oil and half a drachm of spirit of turpentine once in six hours, until it answered. During this and the following day seven pitchy melæna stools were passed.

Dec. 21. After a day's inaction of the bowels, a tea-spoonful of castor-oil was given, and bilious evacuations followed.

Dec. 23 *and* 25. The bowels were relieved by the same small dose of castor-oil, and healthy stools procured. Symptoms of indigestion arose on the 24th, and were yet worse on the 25th, owing perhaps to a rather too generous diet.

The pulse ranged between 100 and 120 (rising even to 130) during the first seven days. But it fell considerably after the first hæmorrhage, and was down at about 90 after the large loss of blood. The tongue also rapidly cleaned, and the thirst gradually subsided. The stomach maintained itself remarkably well until about the 24th. The urine was unusually dark-coloured throughout the whole course of the fever.

From the period of the first hæmorrhage, the patient was seized with the predominant idea of impending death. This feeling was unusually strong on the day preceding the larger hæmorrhages, namely, on Dec. 14th. Yet up to the period of his convalescence, he was not aware that he had ever passed blood by stool. But it should be here mentioned, that on Dec. 15th, slight epistaxis took place, and that he expectorated sputa streaked with blood several times and for several

days. By using red pocket-handkerchiefs, he was kept in ignorance of this fact also. There was bronchial cough for many days.

The patient complained several times of pain about the region of the liver, but having its seat probably in the ascending colon. This was relieved by sinapisms and ammoniated liniment.

There was much throbbing of the head throughout the whole period of the disease. This symptom was much relieved, and sleep induced, by cold spirituous lotions to the forehead.

The value of the acetate of lead was shewn in the sanguineous exudation as clearly as Dr. Graves has proved its power in the diarrhœa of Asiatic cholera.

Remarks. This case is one of much interest; not merely from its severity and the patient's recovery from extreme peril to life, but also as shewing the influence of moral and physical causes on life and organisation. It is matter of observation, that lesion of Peyer's glands is not confined to typhoid fevers, but has been found also in *remittent* fever, sometimes in conjunction with lesion of Brunner's glands in the duodenum. But there is reason to conclude, that such was not the complication in this instance, but that the hæmorrhage resulted from atonic exudation from the capillaries of the mucous membrane of the colon. The hæmorrhage occurred too early in the disease to render ulceration of Peyer's glands probable, although in the malignant form of the disease, in hot seasons and climates, that lesion has occasionally been recognised at even an earlier period. This view is countenanced by all the symptoms of pain and irritation, though never considerable, being confined to the course of the large intestine; and also because both the nasal and bronchial membranes, with their slighter sanguineous discharges, shew that some general cause was at work, seriously damaging the nutrition of the tissues. And here we must invoke not only the miasm of terrestrial or marshy emanations, but also the enervating influence of anxiety and intense application of the mind, to account for the degeneracy of the tissues and the dyscrasy of the blood.[1] An epidemic influence seemed also prevalent in Cambridge at that time, which would further depress the powers of life. Several students suffered from fever, and a friend of my son's, in the same college, died of it. I have also ascertained, that one of the first symptoms which, in his case, created uneasiness, was *hæmorrhage from the nose and lungs*, although it was not to any great extent, and did not continue long.

My son's case was undoubtedly one of low congestive remittent fever; and, looking at the depressing causes at work, it very nearly resembled in its hæmorrhagic tendencies continued fever with putrid symptoms, the hæmorrhage of which, says Dr. Watson, "is strictly of the passive kind, and a symptom of the worst omen."[2] Additional light is thrown upon it by the results of grave surgical injuries, in the shock they give to the nervous system, and through it in their power to disorganize the mass of blood, so that, as Mr. James well argues, "a change ensues

[1] Andral, vol. i, p. 339.

[2] Med. Gaz., vol. x, p. 472. Dr. Roupell insists on two forms of hæmorrhage from the bowels in typhus fever; the one occurring early in the disease, and resulting from increased activity of the vessels; the other in the later stages of the disease, as large passive bleedings. He illustrates the distinction by the two forms of purpura hæmorrhagica. *Roupell on Typhus.*

in every part of the body; and the previously healthy man is converted into a mass of disease."[1]

Dr. John Rose Cormack, in his able treatise already referred to, on the "*Natural History, Pathology, and Treatment of the Epidemic Fever prevailing in Edinburgh and other Towns in* 1843," furnishes a most striking parallelism between the capital features of my son's case, and those which characterized what he calls "the highly congestive form." In the hæmorrhagic tendency, especially, the similitude obtains. Thus, in one of Dr. Cormack's cases, there were epistaxis and black vomit during life, and after death the scalpel revealed the gastro-intestinal mucous membrane here and there dark-coloured, with sub-mucous exudation of blood in patches, and black matter in considerable quantity throughout the entire alimentary canal; in another, hæmorrhage from the vagina; in another, epistaxis and purple spots; in another, black altered blood issuing from the rectum; in another, purpura, and hæmorrhage from the lungs; in another, epistaxis during life, and after death were found softened heart, and dark-coloured gastro-intestinal mucous membrane, with black patches, and sub-mucous exudation of blood; and, in another, hæmorrhage from the rectum during life, while the scalpel revealed considerable effusion of blood under the endocardium of the left ventricle, and vascularity of the gastro-intestinal membrane, with sub-mucous exudation of blood. These post-mortem appearances of the alimentary canal Dr. Cormack interprets otherwise than as evidences of violent inflammation. "In the yellow cases of the fever", he remarks, "now prevailing in Edinburgh, this same altered state of the gastro-intestinal mucous membrane is found; but there is *no lymph effused; nothing, in fact, indicative of inflammation,* unless in some severe cases, which linger long; in such I have seen inflammation around effused clots of blood, which seemed to have been the cause of this, just as any other foreign body might act". (p. 92.) His pathology of the disease recognises, in the earliest stage, "a dissolved state of the blood, and a want of tone in the capillary vessels"; and in the subsequent stages of the disorder, "when the vital fluid is still more dissolved, its increased ability to circulate in the capillaries from the enlarged calibre or relaxed state of these vessels". "Another class of symptoms", says he, "produced by this capillary congestion, is hæmorrhage from the mucous membranes, with occasional black vomit". That the blood is "really in a dissolved state", he infers "from its imperfect coagulation when first drawn by phlebotomy, from the ecchymosis surrounding flea-bites, and other slight injuries of the skin, from the frequent occurrence of purpurous spots, from the hæmorrhages, and from the discoveries by the microscope." (p. 113.)

We were threatened, as a *sequela* of the fever, in my son's case, with serious inflammation of the fascia and periosteum in the upper part of the left leg, during the second week of convalescence; but it was arrested in the adhesive stage by twice applying a few leeches.

Throughout this anxious case I was much aided by my friend Mr. Edward Wallis, whose kindness, ability, and enlightened views of pathology, were a great relief to me in the most trying moments.

Hull, January 1851.

BIBLIOGRAPHICAL RECORD.

Mikroscopische Anatomie, oder Gewebelehre des Menschen. Von Dr. A. Koelliker, Professor der Anatomie und Physiologie in Würzburg. Zweiter Band: Specielle Gewebelehre. Erste Hälfte: von der Haut, den Muskeln, Knochen, und Nerven. Mit 168 Holzschnitten und 4 lithographirten Tafeln. pp. 554. Leipzig: 1850.

[The Microscopic Anatomy or Histology of Man. By Dr. A. Koelliker, Professor of Anatomy and Physiology in Würzburg. First Half of the Second Volume. Woodcuts and Lithographs. Leipzig:[1] 1850.]

The high reputation which Professor Koelliker enjoys as a histologist is amply maintained in the excellent work, of which the first part that has appeared is now before us. The author has been led, doubtless for some good reason, to postpone the publication of the first volume, which is to treat of the elementary tissues. When the work is completed, it will form a perfect encyclopædia of histology, which it will long be difficult to equal or surpass.

The first half of the second volume is divided into four books, containing an elaborate description of the General Anatomy of the Skin and its Appendages, the Muscles, Bones, and Nerves. The structure and development are detailed; and some physiological observations are also added.

The First Book contains a description of the Skin and its Appendages. The cutis is described as consisting of subcutaneous cellular tissue and corium, and containing, in certain parts, muscular fibres, as well as adipose tissue, blood-vessels, and nerves; and the epidermis, as consisting of the *rete Malpighi* and the horny layer.

Professor Kölliker states that he has discovered the existence of muscular fibres in the cutaneous texture, to a much greater extent than is usually described. Todd and Bowman, and Valentin, have mentioned their presence in the dartos; but the author finds them also in the subcutaneous areolar tissue of the penis and perinæum, in the nipple and the areola, and in the hair-follicles and cutis proper in all parts covered with hair. In the dartos and integument of the penis, they are in the form of bundles, loosely surrounded by the areolar tissue. The bundles present longitudinal stripes, and a finely granular appearance, with a great number of very long and narrow, often slightly tortuous nuclei, from about the 11-1000th to the 13-1000th of a line (132-1000th to 156-1000th of an inch) in length; there is also a small admixture of nucleated areolar tissue surrounding them like a sheath; and, very rarely, there are tortuous nuclear fibres within the bundles. These bundles are most large and numerous in the dartos, where they measure from 1-36th to 1-24th of an inch in length, and smallest and least numerous in the perinæum and prepuce. They form a network, which is so thick in the dartos as to constitute a true muscular membrane.

"In the areola and nipple, the non-striated muscular fibre is regularly found, especially in the female sex. The bundles are of the same nature as those in the dartos; but they have no sheath of areolar tissue, nor intermixed nuclear fibres. In the areola, they are arranged circularly in a tender layer, becoming stronger as it approaches the base of the nipple; their breadth reaches to 1-36th of an inch; from this, and their reddish-yellow colour, they are easily perceived by the naked eye. In the nipple itself, they are partly circular, partly longitudinal, and are united into a thick network, through the meshes of which the excretory ducts of the mammary gland appear. The chief part of these muscles lies in the cutis, and forms a good portion of its deeper layer; but a smaller part, especially in the areola,

[1] Published in London by Williams and Norgate, Henrietta Street, Covent Garden; to whom we are often indebted for great facilities in obtaining the latest German works on medicine.

is also seated in the subcutaneous areolar tissue." (p. 14.) This discovery is highly interesting. In his work on *Parturition and the Principles and Practice of Obstetrics*, Dr. Tyler Smith has, reasoning from the discovery by Professor Owen of muscles connected with the nipple in the monotremata and marsupiata, expressed his belief that lactatory sphincters are present in the human mammary gland. If Professor Kölliker's description be found correct by competent observers, there will be supplied what was wanting to prove the truth of Dr. Smith's conjecture. Do these muscular fibres undergo hypertrophy during gestation and lactation? Reasoning from analogy, we should be inclined to answer in the affirmative; in the meantime, however, we can only suggest it as an interesting subject for investigation.

In the hair-follicles, Dr. Kölliker believes muscular fibres to be present in all hairy parts; he has found them on the arm, on the chest in both sexes, in the anal region, in the mons veneris, in the labia minora, the hypogastrium, the thigh and leg; while they are absent from the palm and sole, and other hairless parts.

At pages 42 and 43, we find the following remarks on the elasticity and contractility of the skin: "There has not hitherto been a sufficient distinction drawn between contractility and elasticity. It is not contractility, but elasticity, that explains the gaping of wounds, the retraction of the skin in amputations, etc. On a vital power of contraction depend the wrinkling of the integument of the scrotum and penis, the erection of the nipple, and the formation of the so-called cutis anserina. . . . In erection of the nipple, the areola is narrowed by the contraction of its circular fibres, and the nipple itself is, apparently quite passively, pushed forward. . . . The *cutis anserina*, which consists in an entirely local contraction of the parts of the skin surrounding the hair-follicles, so that the openings of the follicles project in a conical form, is easily explained by the small bundles of unstriped muscular fibre, which I have found to be placed at the side of all the follicles. They pass obliquely from the upper part of the cutis down to the follicle, and, when they act, push forward the latter and retract the former.

"The contraction of these muscles is excited by cold (as in the scrotum, the areola, and in the hair-follicles); or through mental affections, as fright, terror (as in *cutis anserina*); from irritation of the incident nerves of the reflex system (as in the scrotum, and in *cutis anserina*); or through mechanical influences (as in the areola); hence it seems, in part at least, under the influence of the nervous system. The electric stimulus also is effective; in living men, strong local *cutis anserina* and erection of the nipple can be thus produced."

Passing over the sections on the Nails, we find an excellent account of the general anatomy, growth, and development of the Human Hair; from which we extract the author's account of the observations which he has made on the

Changes which the Hair undergoes after Birth. "The process and nature of the change which hairs undergo after birth has hitherto been very imperfectly known. Valentin and Henle, with others, have indeed stated that the lanugo partly falls from the head, and is replaced by new hair; but any more accurate information as to the *when* and *how* of this process has been entirely wanting. I have discovered that, at least in many cases, there is an *entire shedding of the hair* after birth, and that *new hairs grow in the follicles of the primitive hairs, which they gradually push out*, in the same manner as has been found by Heusinger and Kohlräusch to take place in the shedding of hair in animals. The first observations, which led me to the knowledge of what occurs in the shedding of the human hair, were made on the lanugo of a new-born child.

"The hairs here (Fig. 1, 37 in original) all presented a peculiar structure at their lower end. The simple club-shaped or roundish enlargement was not found here as formerly; but from the bulb, which was quite conspicuous, there projected a longer cylindrical process, either somewhat to one side or directly downwards, which at first possessed at one end a depression for

lodging the papilla. Secondly, the hair did not extend in the continuation of the bulb, but terminated in the bulb itself, and was in a peculiar manner very sharply defined by a somewhat thicker little bulb, indented at the edges, and dark like the hair itself. Thirdly, the interior sheath of the root was but just present, or not at all, while the exterior sheath appeared perfectly developed, surrounded the little bulb, formed the proper bulb, and was connected directly with the process above described. The latter, which measured from 45-1000ths to 1-10th of a line, was just of the same structure as the external root-sheath, consisting throughout of small, roundish, nucleated cells without pigment; and it could, from this agreement in structure and from its well-defined connexion with the external root-sheath, be considered as proceeding from the latter. The hairs themselves presented at their lowest part no traces of still tender and roundish cells, such as usually appear, but consisted throughout of hardened elements, like those in the shaft." (pp. 141-42.)

Fig. 1.
(37 in original.)[1]

Professor Kölliker observed these appearances even before the end of fœtal life; but was only able to determine their signification from examining the hairs of a child nearly a year old, where he found evident proof that the extension of the hair-bulb or of the external root-sheath was only preliminary to the formation of new hairs in the follicles of the old ones. The following is his description of the series of changes which take place.

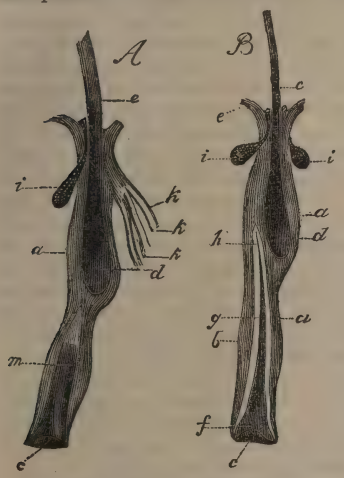

Fig. 2. (38 in the original.)[2]

"If the parts at the base of one of the roots with processes, already described (Fig. 37), be examined, the processes will be observed to become longer and thicker, and to present a separation of the outer and inner cells, like that which has been described as taking place in the planting of the lanugo in the processes of the Malpighian layer of the skin. While the outer cells of the processes remain round, and colourless, the inner ones begin to develope pigment, and to become elongated; and they group themselves together distinctly as a conical mass, with the point directed upwards.

[1] Eyelash from a child a year old, with a process 12-100ths of a line in length from the bulb, or rather from the external root-sheath, and presenting a depression for the papilla. Magnified twenty diameters. *a*. External root-sheath; *c*. Depression for receiving the papilla; *d*. Bulb of the hair; *e*. Its shaft; *e* (on left hand). Transition from the external root-sheath to the Malpighian layer of the epidermis; *i*. Sebaceous glands drawn out with the hair.

[2] Eyelashes from a child, magnified twenty diameters. *A*. Represents a process from the bulb or external root-sheath, 25-100ths of a line in length, with the central cells (*m*) arranged longitudinally, and separated from the external one, forming a distinct cone. *B*. An eyelash in the process of which, 3-10ths of a line in length, the internal cone has become developed into a hair and its internal root-sheath. The old hair is pushed farther out; and, as in *A* and in fig. 37, is destitute of an internal root-sheath. *a*, *c*, *d*, *e*, *i*, as in fig. 37; *b*. Internal root-sheath of the young hair; *f*. Bulb; *g*. Shaft; *h*. Apex of the young hair; *k*. Three perspiratory ducts, opening in *A* into the upper part of the follicle.

At first (Fig. 2*A*, 38*A* of original), this central mass is quite weak, and, like the cellular layers surrounding it externally, easily soluble in soda; but, at a later period, when, like the process which contains it, it has become longer, its elements become harder, and are divided into two parts; a darker inner one, containing pigment, and an outer clear portion. These are nothing else than a young hair, with its sheath (Fig. 2*B*, 38*B* in original); and thus the meaning of the mysterious processes from the hair-bulbs is rendered evident."

"The subsequent development of the *two hairs*, present in the same sheath, is easy to follow. The principal circumstance is, that while, on the one hand, the young hair with its sheaths continues to grow and lengthen, on the other hand, the old hair, which has ceased to grow, is gradually pushed out. A comparison of Figs. 38*B* and 39 will render these processes more easily comprehensible than any description. In Fig. 38*B* the second hair is observed with its apex not yet projecting beyond the internal root-sheath, and surrounded by a moderately long external sheath, while the primary hair still occupies a considerable portion of the follicle. In Fig. 39, *A* represents the young hair, with its point at the opening of the old follicle; the root-sheaths have become lengthened, and the under one has grown upwards with the bulb of the dead hair, which is pushed further out. In Fig. 39, *B*, the young hair has entirely emerged, and appears at the same opening with the old hair, now pushed still farther up. Its internal root-sheath is still more lengthened, and reaches as high as the insertion of the sebaceous and perspiratory glands, which latter open very frequently —sometimes as many as three—into the upper part of the follicle of the eyelids. After this, the old hair soon falls out, while the young hair increases in size and strength, and fills the space left by the old one." (pp. 141-5.)

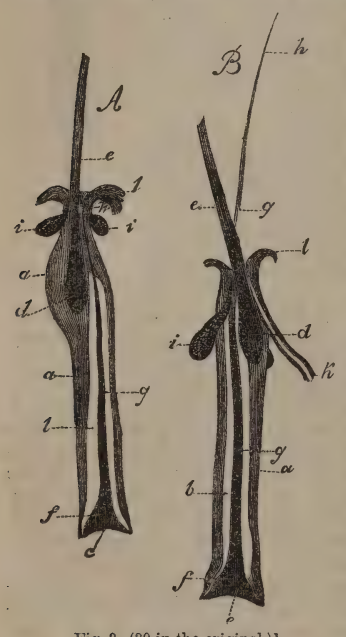

Fig. 3. (39 in the original.)[1]

This description, as yet, applied only to the eyelashes. In the head, and other parts of the body of the same child, the author found only a single hair; but it presented the process of the bulb. He believes it probable that a similar change takes place here also, but cannot decide how soon it occurs; and says that further observations are necessary on this point.

The Sudoriferous Glands mostly consist of single coiled canals; but Dr. Kölliker has found that, in the axilla, the tube generally bifurcates many times into branches, which again divide, and sometimes, but rarely, form anastomoses; they end in blind sacs, after having frequently given some off. The canals are described as thick-walled, and thin-walled. The former possess only an external nucleated fibrous membrane and an epithelium; the latter has within the fibrous sheath a layer of pale muscular fibres, on which the epithelium immediately lies. The secretion of the sweat-glands is said by the author to be not the same in all cases. In most parts of the body, it

[1] Two eyelashes from a child a year old, each containing an old and a growing young hair. Magnified twenty diameters. The references are the same as in the preceding figures.

is a clear fluid; but in the axilla, he has found it either as a greyish transparent slightly fluid substance, apparently consisting of nothing but fine granules and numerous nuclei, or as a yellowish white, tolerably tenacious mass, containing, in variable quantity, large numbers of large, dark, colourless, or yellow granules, nuclei, and cells. The subject of the secretion of the sweat-glands, especially those of the axilla, is acknowledged by the author to require further chemical and microscopical investigation. It will be conceded, on a perusal of his account, to which we must refer our readers, that he has contributed a fair share towards clearing the obscurity.

The Ceruminous and the Sebaceous Glands are next treated of. The author considers that his observations on the development of the latter will be interesting with regard to the question of the formation of glands. They appear during the formation of the hair, as masses of cells continuous with the external root-sheath, and covered by an extension of the follicle. The interior cells begin to form fat-corpuscles; at first these are entirely isolated, but at length they proceed in the axis of the projection as far as the external root-sheath, and an opening is formed into the hair-follicle. The process, in its various stages, will be better understood by a reference to Figs. 36 and 51 of the original work, which beautifully represent the sebaceous glands being gradually developed as diverticula from the hair-follicles.

With the description of these glands, the author concludes the first book.

The Second Book is devoted to a highly elaborate description of the Striated Muscular Tissue. The opinions of Bowman, Henle, Valentin, etc., on the minute structure of this tissue, are commented on, according as they have been confirmed, or negatived by the author's own investigations.

Anastomoses of Muscular Fibres. It has hitherto been generally believed, that the muscular fibres run in a direct course, without dividing or anastomosing. But in 1849, Professor Kölliker described anastomoses in the auricle of the frog's heart. Two primitive bundles were here and there united by a transverse bundle; not by mere apposition, but by a division of the sarcolemma into three separate tubes. Leydig and Hessling have made the same discovery in the invertebrate animals.

The author has since found, that anastomoses of the muscular fibres had been already described and figured by Leeuwenhoeck, as taking place in the heart of the duck, ox, and cod; but histologists subsequently have taken no notice of the occurrence of this fact, with the exception of Frei and Leuckart, and Wagner, who have referred to it as occurring in some of the invertebrata; and it has been more recently and carefully observed in the butterfly by Hessling, and in the *piscicola* and *clepsine* by Leydig. Professor Kölliker and Dr. Corti have found "that anastomoses of the striated muscular fibres evidently occur in the hearts of all vertebrate animals. They are seen in man, in the rabbit, calf, dog, cat, heron, frog, and, according to Dr. Leydig, in the chub. In man, and mammalia, they are very numerous and elegant, and are formed by very short transverse or oblique branches, usually slender, passing between parallel bundles. In the larynx, œsophagus, pharynx, and tongue of the

Fig. 4. (58 in original.)[1]

[1] Ramified primitive bundle, 18-1000ths of a line in diameter, from the tongue of a frog. Magnified 350 diameters.

rabbit, they could not be seen; in the tongue of the frog, immediately under the mucous membrane, there were numerous ramifications of the muscular fibres, but no anastomoses. . . . . In the muscles of the trunk and limbs of man and mammalia, I have seen no trace of anastomoses of the bundles; but it seemed to me as if certain fibres, here and there, were divided into two or more portions, before and at their insertion into the tendons; and I have certainly seen this in the tail of the tadpole." (p. 210.)

The manner in which the UNION OF MUSCLES WITH TENDONS is effected is as yet imperfectly known. Professor Kölliker has made this a subject of investigation; and we shall give an abstract of the results at which he has arrived.

Muscles and tendons are, in some cases, in a direct line; in others, the muscular fibres end at acute angles to the borders or surface of a tendon or aponeurosis, as in the penniform and semi-penniform muscles. The microscopic arrangement is distinct in each of these two cases. In the first, there is no abrupt limit between the muscular and the tendinous fibres; this may be well observed in the intercostal muscles of man. The author has, however, been unable to determine, with complete accuracy, the intimate relations of the structures to each other. He is certain that the sarcolemma does not form a closed sac, but passes without dividing into the tendon; but as to what becomes of it, whether it becomes continuous with the most superficial tendinous fibres, or ends in any other way, he cannot decide, though he is in favour of the view that it ends in the external part of the tendinous bundle. In the interior, the tendinous fibre appears to meet the muscular fibre in the form of a compact bundle; but, with regard to the arrangement of the fibrils, all that the author has been able to make out is, that the transverse striæ become less distinct as the muscular fibre approaches the tendon, while, at the same time, the primitive bundles (fibres) undergo a sort of splitting, as is seen by more or less distinct longitudinal streaks. The transition from muscle to tendon does not generally occur at the same height, and therefore cannot be accurately defined by a straight line.

In the second form of connexion, the fibres end abruptly in cones, more rarely in sharp points, and are set at more or less acute angles on the borders and surfaces of the tendons and aponeuroses. In this case, although there is not a direct continuity of tissue, yet the union is very firm. Professor Kölliker finds "that the ends of the muscular fibres are received into little depressions on the surface of the tendons, while at the same time the areolar tissue between them *(perimysium internum)* becomes continuous with that of the surface of the tendon." These appearances are best seen in muscle which has been kept in spirit, or boiled. With regard to the manner in which the sarcolemma ends, the author states it difficult to determine; but he has sometimes succeeded in distinctly seeing its blind terminations.

We must pass over the remaining subjects treated of under the head of Muscular Tissue, merely observing, that the author gives evidence throughout of his having carefully investigated every point on which he offers any remarks. The observations on the disposition of the fibrils during muscular contraction are especially worthy of being perused with attention.

The Third Book is devoted to a description of Bone; under which head are also included the Cartilages and other structures entering into the formation of Joints. We can merely quote from it the author's account of his investigation on the Nerves of Bone, to which subject he has paid considerable attention.

"NERVES OF THE OSSEOUS SYSTEM. The periosteum is rich in nerves, of which, however, the greater part belongs to the bones. The number of nerves proper to the periosteum itself is tolerably scanty, and Pappenheim seems right in entirely denying their presence in certain parts; at least I have not been able to find any in the inner surface of the vertebral arches, on the neck of the femur, or beneath certain muscles, as the glutæus minimus and peronæi.

Yet there are probably no bones, on certain parts of which they are not found, for I have seen true periosteal nerves on all the large tubular bones, on the flat bones of the skull, on the jaws (especially the alveoli), on the scapula and ilium, on the bodies of the vertebræ, and on the metatarsus. The nerves are in the same layer as the vessels ; they sometimes accompany the larger twigs, sometimes are alone ; and arise, in part at least, from the larger nerves of the bones. Though few in number, and with few ramifications and anastomoses, they evidently spread over a large extent of surface. The primitive fibres measure from 2-1000ths to 4-1000ths of a line ; but, partly through true division, as I have quite distinctly seen in the periosteum of the infraspinous and iliac fossæ in man, and as Czermak has observed in the frontal bone of the dog, and partly by gradual decrease, they reach the size of 12-10,000ths to 16-10,000ths of a line. How these nerves end, I cannot say with certainty. I have seen nothing of loops ; in two cases I thought I saw free endings in points, yet I cannot affirm certainly that they really were such. About many of the joints, as the elbow, knee, and knuckles, I have seen the nerves more abundant than in other parts, ramifying and anastomosing very freely in the vascular areolar tissue above the proper periosteum, and chiefly following the course of the vessels ; yet I could not see here the divisions and terminations of the primitive fibres.

"The nerves have not the same arrangement in all bones. First, in the larger long bones, one or two tolerably large twigs, according to the number of nutritive foramina, pass directly into the medullary canal, where they spread out, following the course of the vessels as far as the apophysis, but not always lying on them ; they ramify abundantly, but, at least as I have seen, form only a few anastomoses. Secondly, all these bones, as I find in opposition to Engel, possess also numerous fine nerves in the apophyses, which pass with the blood-vessels, here very numerous, directly into the spongy substance, and ramify in its marrow. Thirdly, very tender filaments penetrate with the fine arteries into the compact substance of the diaphyses, and here doubtless spread out, although I have not yet been able to trace their course in the firm substance. The arrangement is the same in the smaller long bones in the hand and foot ; only the division into apophysal and diaphysal nerves is not so regular.

"Among the short bones, I found the vertebræ extremely rich in nerves, especially the bodies. They penetrate from behind, in company with the arteries and the basivertebral veins, as well as from the front and sides, and spread out in the medulla of the spongy substance. I saw one or more nervous filaments. I have not yet examined the bones of the carpus, but do not doubt that they also possess nerves.

"In the scapula and ilium, the nerves are very numerous, and penetrate with the larger vessels, partly on the surface, partly in the region of the articular cavities. In the sternum, and flat cranial bones also, the observation of the nerves is difficult. In new-born children, I have seen nerves in the parietal and occipital bones ; and in adults, the parietal and occipital bones are, although sparingly, provided with microscopic filaments, which here and there pass from without, along the small arteries, into the compact substance, and apparently penetrate into the diploë. . . . How the nerves of the bones end, I have not seen ; but this will readily be comprehended by those who know the difficulty of following them in the spongy substance, or the marrow. In two places, I have seen Pacinian corpuscles on the nerves before their entrance into the bones ; on the diaphysal nerve of the tibia before its entrance into the nutritive foramen, and two others on the largest nerve of the metatarsal bone of the great toe, likewise in the neighbourhood of its point of entrance." (pp. 337-340.)

The whole of Dr. Kölliker's remarks on bone, and its accessory structures, are elaborate ; but we have not space for any further quotations from this part of the work.

The Fourth Book treats of the Nervous System. It commences with a

description of the elementary structures—nervous tubules and cells. The arrangement of these elements in the spinal cord, and the origin of the peripheral nerves, are next examined; and some physiological observations are appended. The medulla oblongata, pons Varolii, and cerebellum, are next treated of in a similar manner; and the arrangement of the microscopical elements in various parts of the cerebrum is carefully described. After a notice of the membranes, and an account of the structure of the spinal and cerebral nerves, the book is terminated with the development of the nervous elements. This portion of the work occupies 159 pages; and contains much valuable information on the subject of which it treats; for which, however, we must refer our readers to the work itself.

It now remains for us to say a few words as to the general character of Professor Kölliker's *Mikroscopische Anatomie*. It bears the strongest evidence that the author has spared no pains, either to make himself acquainted with all that has been written on the various subjects of which he treats, or to test the descriptions given by others by his own observations. Hence we find, that the work contains a summary of the views of nearly all those histologists who have made any additions of value to our knowledge of anatomy of the tissues, especially during the last ten, or twelve years. There may be some omissions; but they are certainly very few, and insufficient to detract in the least from the value of the work. The source of every opinion quoted is carefully acknowledged; and frequent bibliographical lists of the authors, who have written on the subjects treated of, are interspersed. Yet the book is far from being a mere compilation. The high reputation which the author enjoys forbids this supposition; and we find evidence throughout that he has examined for himself.

The general plan on which the work is printed is the following. A careful account, divided into sections, is given of the structure and development of each tissue. This part is that which may be read by those who are entering on the study of the various subjects. Every thing is here stated in a clear manner, and to these portions of the work most of the woodcuts—which are excellently calculated to give an idea of the subjects which they represent—are appended. For the use of those who are desirous of becoming more closely acquainted with the literature of the various subjects, a critical abstract is given of the views of previous and contemporary observers, which is printed in a smaller type, so that it may be studied or omitted, according to the inclination and opportunities of the reader.

In conclusion, we can only reiterate our sense of the obligations which all students of histology, both those who are commencing, and those who are more advanced, are under to Professor Kölliker for publishing this work. In Germany it must become the standard work on the subject; nor will the library of any anatomist or histologist be complete without it. We trust that the remaining parts will speedily follow.

On the Crystalline Lens, and Cataract. By Bernard Edward Brodhurst. pp. 243. London: 1850.

There is scarcely any subject which has been more prolific in books than Cataract. At first sight, it might appear difficult to account for this, as the treatment is well understood; and, as to the character of the disease, it generally happens, that what is put forward as new is not true, and that which is true is certainly not new. The explanation, perhaps, is to be found in the fact that such works, in the majority of instances, emanate from gentlemen young in the profession, but who are anxious to make themselves favourably known amongst that extensive and not particularly discriminating class—the public.

After a careful perusal of the work before us, we cannot say that it possesses much claim to originality; though clothed in other language, the

contents are old and familiar friends. Here and there, there is a sprinkling of information from the German schools ; but most decidedly the views given as novel are rather hypothetical than established.

Mr. Brodhurst considers the chief causes of Cataract to be deficient nutrition, and inflammation. Werneck makes a statement which is harder to believe, and if believed, dangerous in practice. He states, that if the intense light produced by the burning of phosphorus in oxygen be concentrated by means of a lens on a Cataract, it may be broken up. He also say, that the retina is not injured. These are statements which appear to us fraught with danger ; for we do not believe that such tricks can be played with the human eye with impunity. We are of opinion, that such a step as that described would set up mischief in the retina, and scarcely fail to produce amaurosis. Dr. Werneck experimented upon animals ; but we need scarcely say, that great caution is requisite in applying reasoning founded thereon to the more sensitive and more highly organized frame of man.

If we understand Mr. Brodhurst correctly, he denies the muscularity of the iris, considering it to be composed of loose cellular tissue and pigment deposit, and defining it as "an irritable membrane without sensation, and its sole function in voluntary motion." Although not identical with the ordinary unstriped muscular fibres, those of the iris have a really close analogy to them ; and the resemblance is strengthened by the fact, that in man, birds, and reptiles, the fibres in all repects are similar to those of the striped muscular fibres ; it is therefore reasonable to suppose, until the contrary can be proved, that the iris is composed of muscular, and not simply cellular tissue.

As regards the disappearance of the Pupillary Membrane, the views of the author are entirely at variance with those entertained by the learned President of the Dublin College of Surgeons. Dr. Jacob supposes it to be absorbed ; Mr. Brodhurst says : "This membrane is not absorbed, as supposed by Dr. Jacob ; but it is ruptured at birth by the action of light upon it ; it is detached from the iris, either wholly or in part, to fall down upon and become adherent to the anterior capsule of the lens ; there it remains, and is never removed." Further evidence will be required, before this view can be accepted. In what way does the author mean that the action of light ruptures it ? Does he mean that the action of the pupil produces the effect ? The mere action of light could not of itself produce such an effect as the tearing of a membrane, unless it excited some expansion or contraction, which immediately acted upon it. The meaning of the author is by no mean clear.

"A mature Cataract", says Mr. Brodhurst, "if allowed to remain *in situ*, is injurious. It may give rise to inflammation, which may unquestionably be propagated to produce cataract in the other eye ; but it is more especially injurious by preventing the passage of light to the retina, by witholding its natural stimulus from the membrane, which, thus long deprived, may never recover its power, or only in part, and that after the lapse of time." (p. 71.)

Although we by no means advocate unnecessary delay in removing a Cataract, we consider that this "unquestionable" fact of Mr. Brodhurst's is very questionable indeed. We have had some experience in these matters, but have never seen anything which led us to believe that a Cataract in a healthy eye gives rise to inflammation which may be propagated to produce Cataract in the other eye. We believe, that where both eyes are affected, it is is simply from the original exciting cause influencing both lenses, and not from any "propagating of inflammation" or anything else, from one eye to the other.

Amongst the exciting causes of Cataract, cold and damp are specified ; and the illustrations are remarkable. An Austrian sea-captain had been in the constant habit, for years, of washing his head each morning with salt-water, and of allowing the hair to dry in the wind whilst he paced the deck of his vessel. Three months previous to his appearance at the Josephinum, his sight had suddenly begun to fail, and he had become rapidly blind with

Lenticular Cataract. Jäger gave it as his opinion, that these repeated ablutions, without subsequent careful drying of the hair, had produced the opacity in question. Subsequently Mr. Brodhurst met, at Rome, with two cases of Cataract, arising under similar circumstances. How far, however, these might have been merely coincidences, or really cause and effect, must remain a question open for further observation to decide, though we apprehend the Byronic mode of dressing the hair, *i.e.*, washing it in cold water, and letting it dry in masses, is far too common to admit of the supposition that it is an exciting cause of Cataract; otherwise the relation between the two would have been long since remarked. We remember once having heard a learned *clinique* given on a certain set of symptoms, described as arising from exhaustion of the system, caused by a superabundance of hair. The symptoms were well marked, the mass of hair was wonderful to behold, the pupils were edified, and the professor satisfied,—when, lo! it was discovered that one slight link in the chain of reasoning was wanting, for though a model in its way, it turned out that the patient wore a wig!

The most interesting portion of Mr. Brodhurst's book is that relating to the practice of the great German oculists Jäger and Rosas. A table is given, by which it appears that, in eighteen years, Jäger has operated on 1011 Cataracts! and of 737 extractions, only thirty-three were unsuccessful; a very remarkable and creditable amount of success. The following is the proportion of unsuccessful cases in the practice of some of the chief foreign oculists.

Jäger	1 in 42	Prochaska	1 in 5
Beer	1 in 9	Roux	1 in 2(!)

Great as is the success of Jäger, we are inclined to think that the practice of the late Mr. Tyrrell was nearly equal during the last years of his life; but Mr. Brodhurst does not make mention of the successful proceedings of his countrymen.

The Surgeon's Vade Mecum. By Robert Druitt, F.R.C.S. Fifth Edition, much improved. pp. 660. London: 1850.

The fact that Mr. Druitt's *Surgeon's Vade Mecum* has reached a fifth edition, is a sufficient proof of the estimation in which it is held by the medical profession. The present work is by no means a mere reprint of former editions, but the author has very judiciously made such alterations as are demanded by the progress of surgical science, though without adding materially to the bulk of the volume. This has been accomplished by expunging some of the explanatory matter, formerly necessary to introduce new facts to the notice of the profession, but now superfluous, as these facts have become current, and their truth generally acknowledged; and by substituting a description of the various improvements which surgery has received during the last three years. The work may be thus considered as offering a very excellent and well-digested abstract of the science and practice of surgery at the present day. There is one feature which distinguishes Mr. Druitt's work from other books of a similar character, namely, that the author draws largely upon the collateral sciences, to add completeness to his subject; and we accordingly find, that while the work is, as it professes to be, a very excellent manual of surgery, it nevertheless displays an intimate acquaintance with the whole field of medicine, and contains a vast mass of information of the greatest utility to practitioners of every branch of the healing art.

As an instance of the care with which the author has collected facts which are sometimes considered of trivial moment, but which are nevertheless most valuable for the practitioner to be acquainted with, we quote the following remarks upon the different kinds of trusses, and the peculiarities by which each is distinguished:—

"There are some cases, in which the common truss fails to keep up a rupture comfortably; and for these the surgeon should be prepared to re-

commend other instruments, which are, for the most part, the property of various individuals, and each of which has some peculiarity, adapting it to particular cases. *Coles's truss* has a spiral spring acting on the pad. The *Moc-Main lever truss* has a simple belt passing round the body, thus dispensing with the usual circular spring; and the pressure on the pad is effected by means of a strap passing under the thigh, and acting on a spring lever attached to the pad. *Salmon and Ody's self-adjusting truss* has a pad revolving on a ball and socket. The *Maidstone truss* allows the pad to slide on the spring, so that the circumference of the instrument may be adapted to the varying size, or movement of the body. *Egg's truss* is said to be made of old sword blades; it is very strong, though not irksome, and requires no fastening. *Adams's graduated pressure truss* has two springs of different curves; by sliding which on one another, the amount of pressure may be varied. In *Tod's truss* the spring goes round the waist, and curves downwards, to compress a pad at the internal abdominal ring. *Newson's wire truss* has a round wire, instead of a flat steel spring, which renders it less likely to be displaced. Trusses may have French pads, which are of an oblong-triangular shape, instead of oval, like the English; or pads filled with air; or may have springs going entirely round the body. But, perhaps, the most ingenious instrument, and that which is likely to be the most useful, is one recently devised by Dr. Arnott; in which, by means of a wire, external to the steel spring, and capable of being tightened or slackened by a nut and screw, the amount of pressure can be regulated with the greatest possible nicety. For children, an *India-rubber band* and pad often answer without a spring. A pad of hard polished wood is recommended by Mr. Dartnell. He also uses flannel, instead of leather, as a covering for the spring, as it can be washed." (p. 470.)

The present edition contains a very well-written chapter upon chloroform, and other means of producing insensibility to pain: and the work concludes with a series of formulæ, which will be found of great value, not only to the student, but to the practitioner engaged in the active duties of the profession.

Observations relating to the Science and Art of Medicine. By William Wegg, M.D. Cantab., Physician to the St. George's and St. James's Dispensary. pp. 233. London: 1851.

After an introduction of thirty-nine pages, upon "Remedies in general", in which the reality of the therapeutic action of medicines is well set forth, the author considers successively, and in detail, the following subjects:—blood-letting, mercury, iodine, antimony, arsenic, iron, colchicum, opium, hydrocyanic acid, stramonium, strychnine, quinine, alimentary canal, and support. Want of space, and the general plan of our Journal, prevent us from giving a critical examination of the many interesting views here presented to our notice; but we have much pleasure in stating, that the work is highly instructive, and proclaims its author to be a sober, sound, and able physician.

Physician's, Surgeon's, and General Practitioner's Visiting List, Diary, Almanack, and Book of Engagements for 1851. Part I for the Library Table; and Part II for the Pocket. London: 1841.

This is the best contrived publication of its class; and does great credit to its editor and publisher. The periodoscope—Dr. Tyler Smith's useful and ingenious instrument—is attached to the inside of the part intended for the pocket.

The Anatomist's Vade Mecum; a System of Human Anatomy. By Erasmus Wilson, F.R.S. Fifth Edition. pp. 656. London: 1851.

We are glad to welcome a new edition of this admirable and beautiful manual, alike adapted to the dissecting-room and the library table.

CRITICAL DIGEST OF THE BRITISH AND FOREIGN MEDICAL JOURNALS.

PRACTICE OF MEDICINE AND PATHOLOGY.

OBSTRUCTION OF THE BOWELS, ARISING FROM A PECULIAR CONFORMATION OF THE SIGMOID FLEXURE OF THE COLON, TERMINATING FATALLY.

Dr. J. A. Easton relates a case of the above description in the *Edinburgh Monthly Journal* for December 1850. The disease under which the patient, a pregnant female, laboured, was supposed to be ileus, and the singular malformation of the colon was not even suspected during life. Active aperients and enemata, administered perseveringly, were employed, necessarily without success; a line of treatment which would not have been persisted in exclusively, had the real nature of the case, which is of comparatively rare occurrence, been apprehended. The most accurate, indeed the only description of this peculiar and rare variation in the course of the colon, which alone Dr. Easton believes to be capable of producing the disease of which this woman died, has been given by Dr. Andrew Buchanan, in the twenty-fourth volume of the *London Medical Gazette*.

The disease may be described as complete obstruction of the bowels, arising from a peculiar, and in most instances congenital formation of the colon, whereby inordinate pressure is exercised on a part of the larger bowel, by a superposed portion of the distended intestine, the result of which is great accumulation of feculent matter, and enormous distension of the belly. The sigmoid flexure, as found after death, in place of passing downwards into the pelvis from the left iliac region, ascended in the mesial line towards the left side, till it reached the region of the spleen, and thence, forming a very acute angle, it descended vertically into the pelvis, having its lower portion, where it runs into the rectum, compressed between the ascending portion of the flexure, distended with gas and fæces, lying before it, and the promontory of the sacrum lying behind it. The disease, caused by this pressure, was more readily induced, and rendered irremediable, by the superadded weight of the gravid uterus. The obstruction in this and similar cases, has been questionably attributed to a twist in the colon, at the lower end of its sigmoid flexure; but in the present instance, this view must be abandoned, simply because no twist existed; the work of impediment having been more effectually performed by a column of nearly solid intestine, pressing heavily on another portion, in contact with the promontory of the sacrum, and the gravid uterus forming the copestone of the whole.

The symptoms of this disease, of a common or general character, are, constipation and dragging pains in the back. The pathognomonic symptoms are the intractable and continuous nature of the constipation, the enormously distended belly, the empty rectum, and the excruciating pain, unaccompanied by fever, or other sign of inflammation. Dr. Easton very ingeniously and candidly observes that these ought to have enabled him to distinguish the disease from all other kinds of tympanitic swelling and constipation. We think, however, that the writer scarcely does justice to himself here; and we have very grave doubts about the facility of making a correct diagnosis in such cases. The fatal result, in Dr. Easton's case, was attributed to the persistent and excruciating pain, for inflammation was not present; and, as Dr. Buchanan has well remarked, "mere obstruction cannot be considered as an adequate cause of death, since persons have been known to live more than a quarter of a year without any alvine evacuations."

Dr. Easton, having no observations of his own to offer regarding the treat-

ment to be pursued in similar cases, avails himself of the remarks of Dr. Buchanan, who, looking on all purgatives, as well as clysters, as utterly useless, except for the purposes of emptying the rectum, observes that the first and great object of treatment should be to remove the mechanical obstacle to the evacuation of the bowels. With this object, he advises that the patient should be placed upon the hands and knees, or standing with the body inclined forward, which has the effect of freeing the end of the colon from the weight of the first turn of the sigma lying over it. He then employs an œsophagus tube, armed with a large sponge, fastened to the end, by means of a string attached to it, and passing through the tube, while, by means of the other half of the string running outside the tube, the sponge can be withdrawn, when we wish to use the tube as an injecting instrument. In the first instance, however, it is to be used as a probe and dilator. On withdrawing the instrument, we shall ascertain if it has passed the obstruction, by observing whether its point be smeared with fæces. If it have passed, we should reintroduce it, and by passing and repassing it through the compressed part, we should endeavour to form a free passage, by making an indentation in the soft feculent mass, lying before it. If this does not succeed in producing a discharge of fæces, the tube should be carried up as far as possible, the sponge withdrawn, and tepid air or water injected, as may be best found to answer the purpose. Should this plan not succeed, Dr. Buchanan advises, rather than leave the patient to his fate, that the bowels should be punctured with a small trocar, not with the view of evacuating the fæces, which could not be prevented from escaping, in part, into the peritoneal cavity, and so causing death ; but solely with the object of discharging air from the bowels, which will both relieve the sufferings of the patient, and facilitate the subsequent attempts to evacuate the fæces through the natural passages. The point recommended for puncture is about the middle of the right colon ; as that part of the bowel is most uniform in its seat, and is almost entirely distended with air. Operations for the formation of an artificial anus, by opening the colon in the situation here indicated, behind the peritoneum, in ileus and intusceptio, have been performed since Dr. Buchanan wrote. This operation may be added to our remedial resources in cases resembling the one described. Dr. Easton evidently, and we think justly, regards the ingenious treatment of Dr. Buchanan as mainly palliative and provisional.

FÆCAL OBSTRUCTION OF THE BOWELS MISTAKEN FOR OVARIAN DROPSY : EXTENSIVE TUBERCULAR PERITONITIS.

In a series of papers on the Diagnosis of Ovarian Dropsy, Mr. I. B. Brown relates the following case in the *Lancet* for July 13th, 1850.

Case. Miss F., aged 14, born in India, was brought to Mr. Brown on March 22nd, 1849. She had never menstruated ; had generally good health, but had always suffered from flatulence and distension of the bowels. Five weeks ago, great languor appeared, with rapid growth, and emaciation about the neck and shoulders. She complained of uneasiness in the left side, and that her dresses were too tight. On March 9th, an obstetric physician was consulted, who considered it a case of ovarian dropsy. He prescribed aperient pills of rhubarb and galbanum, and tincture of muriate of iron, and recommended her to wear a calico belt to support the abdomen. The remedies were persevered in, yet she daily got worse. The pulse became quick, 120 ; there was hectic flush of face, and increased languor, and the abdominal swelling rapidly increased.

On March 22, Mr. Brown found a tumour in the left iliac fossa, and fluctuation perceptible over the abdomen, below the umbilicus. On more careful examination the next day, he discovered a solid tumour above and just to the right of the umbilicus. She had passed a restless night ; skin

hot; pulse 120; tongue red, not coated; dejections very frequent, but slight, of a pale chalky colour; urine very scanty; extreme languor; general tenderness, especially at the point of the hardened tumour. She was ordered three grains of grey powder, and four of Dover's powder, at bed time; and chalk mixture, with decoction of bark and aromatic confection; also to have the abdomen rubbed with a mercurial embrocation on going to bed. On the 24th, the countenance indicated great bodily and mental depression. The medicine was continued; and the recumbent posture was enjoined. On the 25th, she evacuated an enormous quantity of hardened fæces, after which the solid tumour disappeared. Mr. Brown was now certain that there was no ovarian tumour, but that the fluid in the abdomen had arisen from chronic peritonitis. She appeared to improve slightly until the 8th of May, when she was suddenly taken worse, with shivering, sickness, pain in the abdomen, and sickness of pulse. There appeared to be ulceration of the intestines; but she lingered till the 22nd of June, when she died.

Post-mortem Examination, fifteen hours after Death. The whole body was extremely emaciated; there was no protuberance of the abdomen. On opening this cavity, there was a quantity of thick, offensive, purulent matter diffused throughout. The small intestines were rolled up into a compact ball, and so glued together by adhesions, that it was almost impossible to separate them. The whole of their serous surface was covered with tubercular deposit. This mass of intestine was fixed to the upper portion of the abdominal cavity. The lower part of the abdomen was filled with a quantity of highly offensive, dark grey-coloured, semi-liquid matter, being a mixture of pus and fæces. On separating the transverse colon from its strong adhesions, an ulcerated opening, of the size of a sixpence, was found in it, with well defined edges, having a distinct greyish-black rim. On further search, two or three other smaller perforations were detected. Purulent matter was infiltrated throughout the mass of tubercular deposit. The peritoneal coat of the uterus was diseased; the ovaries were of their natural size, and healthy. The liver was healthy, but its peritoneal coat was diseased. The omentum was matted to the intestine by adhesions. The thoracic organs were healthy throughout.

CONDITION OF THE NERVOUS CENTRES, ETC. IN HYDROPHOBIA.

Case 1. Dr. J. A. Sidey relates in the *Edinburgh Monthly Journal* for December 1850, an accurately detailed case, terminating of course fatally, although various energetic remedies, including Indian hemp, Battley's solution, venesection, mercury, caustic, issue in the scalp, were employed. Anæsthesia produced by chloroform was tried, but could not be persevered in, from the accumulation of mucus in the throat and mouth, which produced urgent dyspnœa.

The body was most carefully examined after death by Dr. Hughes Bennett, who had suggested, in the *Library of Medicine*, that most of the symptoms of Hydrophobia might be caused by irritation at the roots of the eighth pair of nerves. But on the most careful examination of different portions of their structure, and of the restiform ganglion, as well as of several portions of the white and gray substance of the cerebrum, cerebellum, and spinal cord, with a microscope, under a power of three hundred diameters, not the slightest change from the healthy character could be distinguished. The circumvallate and fungiform papillæ at the base of the tongue were greatly elongated and enlarged. The salivary glands were also enlarged. The mucous membrane of the fauces and upper part of the pharynx was of a purplish-red colour. The membrane lining the trachea and bronchi to their ultimate ramifications was of a deep-red mahogany colour, and covered with san-

guinolent frothy mucus, which completely filled up the smaller ramifications. The lungs, the heart, and all the abdominal organs, were apparently healthy.

Case II. Dr. James Struthers relates, in the same journal, for January 1851, a case, occurring in a boy. In the case just detailed, there was great sensitiveness of any movement of the air; and a gust of wind, blowing on the patient, caused him to sigh frequently. In the present case, Dr. Struthers says, that while holding the hand of the patient, he blew suddenly in his face, when he sprang, convulsed, to the other end of the bed, covered himself with the clothes, shook and cried very much, and entreated that he would not breathe on him any more. *This established the diagnosis.* In both cases, active symptoms of the disease became manifest after a fright, about a month after the patients had been bitten.

On examination of the body after death, the membranes of the brain were found healthy; but the cerebral substance, both white and grey, was very slightly and uniformly softer than usual. The superficial vessels of the cerebellum and medulla oblongata were generally and pretty fully congested; the grey matter of the cerebellum was rather deeper in colour than natural. Careful examination detected nothing unusual in the cranial nerves, especially the pneumogastric, both where it leaves the medulla oblongata, and at its place of origin in the floor of the fourth ventricle. The same slight general softness, which was observed in the brain, existed in the cord, but to a less extent. The medulla oblongata was normal, and firmer than any part of the cord. The sublingual glands were natural. The trachea throughout was coated with a sanguinolent froth. Congestion, ecchymosis, and emphysema, were found in the lungs, bronchi, and trachea; these are the morbid changes most constantly found in man and animals that have died of this disease, and correspond in frequency to one of the most constant of all the symptoms, viz., convulsions of the muscles of respiration, to which they may fairly be attributed. The mucous membrane of the pharynx and œsophagus was quite natural. The most uncommon appearance was the frothy state of the blood in the right cavities of the heart, previously noticed only by Morgagni and Trolliet. There was absolutely nothing about the nervous centres and roots, which could indicate that the disease was other than a purely functional affection of the nervous system. The eighth pair of nerves were remarkably free from any appearance of disease.

Excision of the lacerated parts, and subsequent cauterisation with the nitrate of silver and pernitrate of mercury, were performed an hour and a half after the patient was bitten, a fact incontestably proving that absorption may take place within that time.

CASE OF COMMUNICATION BETWEEN THE STOMACH AND EXTERNAL SURFACE OF THE ABDOMEN.

Dr. William Robertson relates the following interesting case. Isabella Davidson, an unmarried woman, aged 36, was admitted into the Royal Infirmary of Edinburgh, in November 1850. In 1842, she first observed a tumour in the left side of the epigastrium, not exceeding a pea in size, hard, painful, and tender, which in the course of two years steadily increased to the size of an orange, when it began to subside, and in three months completely disappeared. In a month afterwards, a dark spot, of the size of half-a-crown, appeared in the epigastrium; and then, for the first time, the patient's health began rapidly to give way. On the 22nd of October, 1844, the black spot gave way, and the contents of the stomach escaped from the rent. Water and milk, when swallowed, gushed out from the opening. By the end of January following, the aperture had completely cicatrised, and continued closed for about a year. Early in 1846, the cicatrix became red, and the opening was re-established by ulceration. In a few months the fistula

again cicatrised; but in June 1847, ulceration occurred for the third time, and the communication with the stomach has existed ever since.

For the last three years, she has lain almost constantly in bed, and has worn a piece of linen, secured with a pad and bandage, over the external orifice. Her appearance is perfectly healthy, her appetite good, and the bowels habitually costive. She is cheerful and intelligent, and sleeps well.

The external perforation is situated about 2½ inches from the median line, and 3¼ from the umbilicus, close to the cartilage of the eighth left rib. It is of an oval form, and will admit an ordinary-sized thumb. Its margin is rounded, depressed, hard, and red, presenting minute points of ulceration. The surrounding integuments, to the extent of two inches, are red and indurated, and, in a few points, excoriated. On passing the little finger deeply into the orifice, it meets with resistance; when turned downwards and to the left side, in the direction of the pylorus, it passes freely. The mucous membrane of the posterior wall of the stomach can be seen, when the patient is placed in a favourable light; and when she takes a mouthful of milk, it can be observed to flow over the surface opposite to the external orifice. It is believed that the perforation communicates with the stomach through its anterior wall, not far from the great curvature, and probably about four inches from the cardia. The case probably does not admit of remedy; but, from its resemblance to that of Alexis St. Martin, the propriety of instituting some experiments on digestion has been suggested, and a hope is held out that the results may be communicated, at some future period, to the profession. [*Edinburgh Monthly Journal*, January 1851.]

CASE OF INTERMITTENT FEVER WITH INTERVALS OF NINE DAYS.

Dr. Bertrand relates the following case in the *Deutsche Klinik* for Nov. 16, 1850. Although intermittent fever is endemic in the district of Rheingau, where he has practised for ten years, he has never met with a similar case, nor does he find any recorded in the works of other authors. It is remarkable for the duration of the paroxysm and the apyrexia for eight times twenty-four-hours, and for the invasion of the new paroxysms on the ninth day.

Case. Mrs. M., aged 65, had suffered in her earlier years from an affection of the heart with asthmatic symptoms, for which she had frequently been bled. She was seized last June with inflammation of a cutaneous tumour on the left parietal bone, which had existed without inconvenience for fifteen years. She had previously complained for some weeks of pain in the epigastrium. Dr. Sturm, who saw her, found the tumour burst, and discharging some thick matter. While this was going on, and simple local treatment was being applied, the patient was suddenly one evening seized with rigors, followed by violent heat, and delirium. Greater turgidity was manifested in the head; and on the next day, there were fever, constant efforts to vomit, and pains in the limbs, during which there appeared a very red and glistening erysipelatous swelling, commencing at the left ear, and extending over the nape of the neck, the hairy part of the head, the forehead, and the entire left side of the face. The pains in the limbs then ceased, and the dry heat was replaced by a copious and universal sweat, which continued for three days, along with saturated but clear urine. At the same time, the erysipelatous swelling diminished, and disappeared on the fourth day without desquamation. The patient then felt tolerably well, with only some oppression about the head, much thirst, and an irregular pulse—which, however, she stated to be usual to her.

On the ninth day—reckoning that on which the rigors appeared as the first—she was again seized, after pain in the back and lassitude, with a slight rigor, followed by a more intense hot stage, with congestion of the head and delirium, so that she did not know where she was, nor recognise those standing around her. The symptoms declined much in the same manner as before

related. On the ninth day, the rigor again returned, but more severely ; and the urine in this attack, for the first time, deposited a reddish-yellow sediment. In the same manner, four other paroxysms occurred, notwithstanding the employment of sulphate of quinine, which, however, was given in too small doses.

Towards the end of the seventh attack, Dr. Bertrand was called in consultation. He could see no traces of erysipelas. There seemed to be no remarkable enlargement of the spleen. The pulse was irregular. He prescribed sulphate of quinine, to be taken in doses of ten or twelve grains, on the day before the expected return of the paroxysm. The attacks gradually diminished in intensity, still retaining the nine days' type ; and the patient recovered.

THE PARALYSIS WHICH SUPERVENES DURING CONVALESCENCE FROM PNEUMONIA.

In the *Bulletin Général de Thérapeutique* for December 30, 1850, Dr. Macario describes a form of Paralysis, which he has observed to occur during convalescence from acute pneumonia, and which he terms Pneumonic Paralysis. He relates two cases in illustration.

Case I. J. M., of Samerques (Cher), a day-labourer, aged 49, of nervous temperament and feeble constitution, badly lodged and fed, took cold in the beginning of February 1850 ; and, in a few days, he felt a violent stitch in the side, under the right breast. Two days after, on February 10th, Dr. Macario was called to him. There was crepitant rhonchus at the posterior and inferior part of the right lung, with slight dulness ; the sputa were viscid and sanguinolent, the tongue yellow, thirst severe, the breath of a peculiar odour, which Dr. M. has many times observed in pulmonary fluxes ; there was intense fever. He was bled largely, and an emetic was administered, which produced vomiting and bilious stools. He went on well for several days.

February 15. The patient had a relapse. The voice was hoarse, the respiration was quickened, and the tongue had a tendency to become dry. Sibilant rhonchus was heard in the posterior part of both lungs, especially the right, where there was also some sub-crepitant and humid rhonchus. The patient had perspired much during the night ; the pulse was 96. A large blister was applied over the right scapula, and a mixture of white oxide of antimony, which the patient had been taking, was continued.

February 18. The patient complained of great prostration : his voice was slow and very weak, and the cough continued. The sub-crepitant rhonchus at the posterior part of the right lung still continued.

February 19. The voice was still more feeble and broken, the tongue was red at the edges and white at the centre, and rather dry : the sub-crepitant rhonchus had extended, the sputa were yellow and thick, and the pulse 72.

February 23. The patient was convalescent, and commenced to take some nutritious food.

February 28. There was not the least trace of pulmonary affection. The blister had continued to suppurate abundantly ; the surface was covered with a white exudation. The patient also complained of lassitude in the legs, and of a creeping sensation in the soles and palms ; he also saw objects double.

March 6. The blistered surface had not healed, but rather kept increasing in extent. The weakness of the limbs had also increased, and the creeping sensation had extended up the legs as far as the groins, and up the arms as far as the shoulders.

April 26. The blistered surface, though less in extent, was still suppurating. The weakness of the limbs had gone on increasing from below upwards, and they were now heavy, and bent under the weight of the body. The patient

had walked with difficulty, for three weeks, with the aid of a stick; but the creeping sensations having extended over the whole of the limbs, and the muscular weakness having constantly increased, the patient was obliged to use crutches; and finally, in some days, was quite unable to walk. He could not move the lower limbs; and, when let go after being lifted, they fell as if dead, being completely paralysed. The arms, although so far weakened as to render him incapable of feeding himself, always, but in a vague and uncertain manner, obeyed the will. Sensibility was perfect; and there had never been any sensation of coldness in the paralysed limbs.

The patient remained in this state of muscular paralysis for about a month; until one night, towards the end of May, he felt a sensation of cold in the legs, so that he could not warm them; and, in the morning, he was able to move his feet a little. The improvement continued; and at the end of a fortnight he could get up, and walk alone. He soon recovered the complete use of his limbs; but the creeping sensations continued until the end of June, about a month after his recovery from the paralysis. This patient never had head-ache, nor any pains in the region of the spine.

Summary. This was a case of amyosthenia (paralysis of motion), occurring during convalescence from a severe attack of pneumonia. It commenced by simple muscular weakness, which at last successively attacked, *from below upwards*, the whole of the limbs. The paralysis was complete in the lower, incomplete in the upper limbs. The intellectual faculties were entire throughout; there was nothing peculiar in the state of the spinal cord. The paralysis was therefore entirely local, and presented some analogy to hysterical paralysis; and this circumstance rendered the prognosis favourable. The absence of symptoms referrible to the nervous centres, together with the transient diplopia which accompanied the onset of the affection, pointed to the purely functional nature of this new kind of paralysis.

Case II. B., aged 35, a weaver, was taken ill, with symptoms of pneumonia, on the 24th May 1850. We omit the daily reports of this case, observing merely that a friction sound, indicating pleurisy, was discovered on the 26th; that a large blister was applied to the right side of the back on the 31st; and that the patient went on favourably up to June 9th; the blister, however, still continuing to suppurate.

June 29. The blister still remained open. Five or six days ago the patient was seized, about 3 A.M., with an acute pain in the epigastric region, radiating to the right shoulder and arm, and soon disappearing spontaneously.

July 22. The blister had ceased to suppurate only a few days previously. The patient now complained of sore-throat; and for eight or ten days he had felt great and increasing weakness in the legs and arms. At this date, when he raised his arms, the hands remained flexed on the fore arms; the movements of these limbs were vague and uncertain, and, in spite of all his efforts, the patient could not raise them to his head. For two or three days he was unable to move. When the legs were lifted, and then let go, they dropped like dead bodies. Sensibility remained perfect. The appetite was tolerably good; but there was obstinate constipation. There was no pain in the head or spinal region. The intellect was unaffected. In spite of tonic regimen, and the use of iron, the paralysis increased rapidly; and the patient died on the 24th of July. No autopsy was permitted by the friends of the patient.

Summary. The two lungs were successively seized with inflammation, and on this supervened pleurisy of both sides. In spite of this formidable array of symptoms, a vigorous antiphlogistic treatment was crowned with unexpected success. The patient's appetite returned, and he was able to walk about; only he complained of great weakness in the arms and legs. He was supplied with some good wine to restore his strength; but the debility made rapid and deadly progress; and, at the moment when he was thought safe, he was seized with that paralysis which soon brought him to his grave.

Remarks on the Cases. Dr. Macario asks—what is this paralysis? What is its cause, its rationale, and its seat? Does it depend on an encephalic or on a local influence? Is its proximate cause to be sought in the exhaustion produced by the prolonged and abundant suppuration from the blistered surface? Can it be referred to the action of the brain and spinal cord? These are questions which it would be impossible to answer at present. There was nothing remarkable in the state of the nervous centres: and the author observes, that blisters sometimes go on discharging for as long a time, and as abundantly, without giving rise to paralysis. Besides, are blisters and cauteries, when kept open for years, ever followed by similar effects?

The paralysis appears to have had its seat in the nervous and muscular system of the affected limbs. There was, as has already been observed, an absence of symptoms referrible to the nervous centres; the intellect and volition remained entire; the *fourmillements*, and the muscular weakness, commenced at the palms and soles; that is to say, at the peripheral extremities of the nerves, and gradually proceeded upwards. Dr. Macario believes that, if he had made an autopsy of the fatal case, he would have found nothing to account for the paralysis and death.

In his concluding remarks, the author justly observes, that many cases must be collected before any conclusions are drawn as to the true nature of this affection.

HYDROCHLORATE OF LIME IN SKIN-DISEASES.

The Hydrochlorate of Lime, which exists in many mineral waters, is rarely employed in medicine. It is, however, a valuable remedy, and, according to M. Cazenave, may frequently be substituted for the iodide of potassium. It has moreover the advantage of being easily borne, and may be continued for some time. Biett used it in scrofulous lupus. For some time, M. Cazenave has used it very extensively, especially in cases which have exhibited a predominance of the lymphatic temperament. Thus, in chronic eczema, and especially in impetigo, he gives it in doses of two grammes a day. He gives the following formula: R. Crystallized hydrochlorate of lime, fifteen grammes; distilled water, five hundred grammes. A tablespoonful to be taken three or four times a day. [*Annales des Maladies de la Peau*, as quoted in *Bulletin Général de Thérapeutique*, 30th November, 1850.]

ACONITE IN PAPULAR ERUPTIONS (LICHEN AND PRURIGO).

M. Cazenave states, in the *Annales des Maladies de la Peau* for October 1850, that he has seen Biett employ Aconite with success in secondary syphilis, especially to mitigate the pains in the bones. Believing that a main indication in the treatment of papular affections of the skin is to combat the hyperæsthesia, M. Cazenave has successfully employed the extract of aconite, in daily quantities of from five to ten centigrammes (about three-quarters of a grain to one grain and a half.) Under this treatment, he has found the itching to diminish rapidly, and then to cease; and at the same time the eruptions have disappeared, which were kept up by the irresistible desire to scratch, and aggravated by the action of the nails.

He uses the following formula: R. Alcoholic extract of aconite and extract of taraxacum, of each one gramme (fifteen and a half grains); to be divided into forty pills. One or two to be taken morning and evening. [*Bulletin Général de Thérapeutique*, November 30, 1850.]

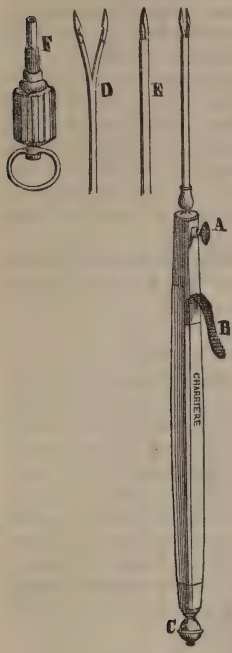
LEAD-COLIC.

Mr. Workman mentioned, at the Reading Pathological Society, a case of hæmoptysis, in which the exhibition of acetate of lead had been followed by severe colic and constipation for nine days, which was at last relieved by warm baths; and Dr. Wells alluded to a case of melæna, where the same effects had occurred. [*Prov. Med. and Sur. Journal*, December 1850.]

SURGERY.

REMOVAL OF FALSE MEMBRANES FROM THE EYE.

Mr. W. R. Wilde of Dublin has recently invented (and described in the *Medical Times*), a very simple and beautiful instrument for the removal of opaque capsules and false membranes from the chambers of the eye. The extraordinary toughness of these formations often renders their division very difficult, but the difficulty will be materially lessened by the ingenious contrivance before us; which is truly a valuable addition to the means and appliances of ophthalmic surgeons.



A strong spiral spring is attached to the end of a fine double canula, and passes through an ivory handle, to be fixed at the end by a ball nut C. B is a spring whereby the long canula is pressed forward through the short one, which is attached by the small screw A to a metal plate at the end of the handle. The part D consists of a fine steel stem, the end of which is cleft, and each extremity forms the blade of a fine pair of shears scarcely a line and a half long, and these, properly adjusted, cut with the greatest precision. When the instrument is used, the spring B being pressed by the middle finger, the long canula is projected through the collar, and the blades of the scissars close with a clipping motion. When B is relaxed, the canula is retracted by the coil, and the blades divaricate. When the canula is pressed forward, and the blades are closed, they form a needle-like point E. F is a key to fix and screw up the spring B.

Mr. Wilde recommends that an opening should first be made for the passage of the instrument, either with a flat needle or extraction knife.

OPERATIONS FOR STRANGULATED HERNIA IN OLD PERSONS.

Mr. W. H. Livett, of Wells, Somersetshire, has published in the *Medical Times* for January 4, 1851, two cases of operation for Strangulated Hernia in persons of advanced age. Both patients were females; one was aged 76, and had inguinal hernia; in the other, aged 79, the rupture was femoral. The after-treatment consisted in the cautious administration of moderate doses of castor-oil, and in the early use of a stimulant and nourishing diet.

Mr. Livett agrees with the opinion of Mr. T. B. Curling, expressed in his paper on the above subject in the London Journal of Medicine for June 1850, as to the advantage of nourishment, and even stimulants, at an early stage after operations for Strangulated Hernia in old people. He believes that when the operation is performed early, before the powers of life are much depressed by the symptoms of strangulation, and when our attention is directed rather to sustain enfeebled powers than to prevent inflammation, advanced age should not *per se* induce us to form an unfavourable prognosis in such cases, or lead us to hesitate in using the only means in our power to prolong life.

OBSTETRICS.

DR. JAMES REID ON PROLONGED UTERO-GESTATION.

The following is an abridgment of some observations made by Dr. James Reid, in an interesting essay on the Duration of Pregnancy in the Human Female, lately published in the *Lancet*. The part to which we more particularly refer is contained in that journal for July 20th, 1850.

Dr. Reid having, in the previous part of his essay, carefully examined some alleged instances of very prolonged gestation, concludes that " in the great majority of them there were cogent reasons on the part of the women for intentional deception, whilst, in the others, various sources of error have been pointed out, which probably led the patients to deceive themselves; and we cannot therefore allow such very exceptionable cases to weigh against the present experience of the whole medical profession. But we may still inquire whether the usually-received period of gestation may not occasionally be exceeded, to the extent of some days. In the Gardner Peerage case, five of the medical witnesses only were opposed to protracted gestation."

The two principal arguments which have been urged against the possibility of protracted gestation are, that " Nature is certain in all her laws," and that " this is evidenced *in the lower animals* in relation to the very point in question." In answer to the first objection, it may be replied, that the natural functions of the womb itself vary considerably in relation to time. The periods of menstruation, and the intervals between the periods, are by no means the same in females; the intervals, indeed, vary not only as to days, but in some individuals to the extent of one or two weeks.

The periods of dentition, of puberty, of decrepitude, are not immutable as to time; there is a general rule, but the exceptions are by no means unfrequent. The power of reproduction itself varies to a considerable extent.

The certain and definite period of gestation in the lower animals has been received as an axiom since the time of Aristotle. His assertion was implicitly relied on for centuries. A few writers, indeed, ventured to question the fact, but it was reserved for Tessier and Earl Spencer to prove, by extensive statistical tables, that the statement as to a fixed definite period for gestation in animals is totally opposed to facts; and the question as to this point may now be regarded as definitely settled. Tessier showed, that in 160 cows the average duration was nine months and ten days; and in mares eleven months and ten days. Of the 160 cows, 68 went beyond the 280th day; some of them to 290 days; 20 went on to 300, and 5 to 308 days. The same deviations occurred as to the term of gestation in mares. Lord Spencer published the result of 764 instances of the gestation of cows, in the *Journal of the Agricultural Society*, from which it appeared, that " the average term of gestation in cows is 285 days." Of the 764 cases, few exceeded that period by more than five or eight days; eight only exceeded it by more than twelve days, and one only went to the eighteenth day beyond. It has been shewn also that in the elephant, sow, bitch, cat, goat, sheep, &c., the usual period of gestation is occasionally exceeded by two or three weeks.

The following table (see next page) of the cases which have fallen under Dr. Reid's notice will serve to shew that the usual duration of pregnancy in woman is about 275 days, rather than 280.

It will be seen that there are well authenticated instances in which the period of gestation has been extended beyond the usual term. In the cases of *single intercourse*, 293 days form the longest period, or eighteen days beyond what Dr. Reid believes to be the usual average duration of pregnancy in the human female. In Lord Spencer's tables, the greatest excess beyond the average term of gestation in the cows (285 days) was also eighteen days. The cases of Dr. Ashwell and M. Velpeau may be considered as doubtful, being without sufficient dates.

DR. REID'S TABLE OF THE DURATION OF PREGNANCY IN THE HUMAN FEMALE.

No. of Case.	Last appearance of Catamenia.	Date of Connexion.	Confinement.	Period of gestation. Days.
1	—	July 27	April 30	276
2	March 14	Mar. 18 & 20	December 20	274

[3] Quickened, June 16th.
[4] Quickened, November 10th.
[5] Quickened in 19th week.
[6] Sickness commenced, April 14; quickened, July 6th.

With a view to ascertain the experience of those who were most likely to have paid particular attention to this subject, Dr. Reid applied to upwards of forty of our most eminent obstetric practitioners in London, Dublin. and Edinburgh. The large majority were firmly convinced of the occasional extension of the usual period a few days beyond 280. Several, like Dr. Reid, had met with one or two cases only of protracted gestation, out of many hundred, on the exact data of which they could rely. Others, who had not kept notes of their cases, could not positively speak to facts, but had no moral doubt as to the period being extended in some instances. Some, who had extensive experience in private and hospital practice, had never met with an undoubted case of protracted gestation; whilst two affirm that it is their strong conviction that no case ever exceeds the 280th from conception; and one, that it is never carried beyond the ninth calendar month.

DR. JAMES REID ON THE CALCULATION OF THE PERIOD OF EXPECTED PARTURITION, FROM THE LAST APPEARANCE OF THE MENSES.

In the essay above referred to, Dr. Reid makes some remarks on the above subject, of which the following is an abridgment.

Obstetric practitioners most frequently calculate the probable time of parturition from the last appearance of the menses. But in whatever method the calculation may be made, occasional circumstances will greatly interfere with this mode of calculation. 1. A discharge so exactly resembling the menses as not to be distinguished from them by the female, if not in reality identical, may occur every month regularly, as to time, quantity, and interval, during pregnancy. 2. The catamenia may be accidentally arrested by other causes than pregnancy for months, and even years, and impregnation may occur at any period during this stoppage. 3. This accidental stoppage may alone give origin to all the general symptoms of pregnancy, such as morning sickness, tumidity of the breasts, of the abdomen, etc.; and this combination of symptoms may be sufficient to convince the female, as well as her medical attendant, that she is pregnant, when in reality she is not so. Even the fœtal movements have been felt, and graphically described, when the existence of the infant was in the imagination only. Supposing this state to continue for nine months, that at the expiration of this time impregnation really did take place, and that gestation continued for its usual period, it would be difficult to convince the patient that she had not been pregnant during the whole eighteen months.

Again, a female whose catamenial period has always hitherto lasted for five or six days, finds that it is on some particular occasion arrested, after a slight appearance for one day only, or even for a few hours. She looks upon this unusual deviation as a token of pregnancy, regarding the discharge as accidental, and reckons from the period previous to it. At the end of the ensuing month, no appearance whatever is seen, and this confirms her in her original suspicion. Her parturition is expected at the end of nine months, dating from the last full period, but does not take place until nearly two months after this epoch; the explanation being, that impregnation did not occur until a day or two previous to the total stoppage of the expected menstrual discharge. The error may be still greater, should this scanty discharge have occurred more than once, and have been regarded, each time, as an accidental occurrence of the pregnant state. On the other hand, cases of pregnancy are met with, in which such an accidental monthly discharge has taken place for a few hours once or twice, and, from erroneously regarding it as a proper catamenial period, the child has been born much sooner than the anticipated time.

Dr. Reid distrusts, therefore, any exceptional cases of prolonged gestation, the principal datum of which is the last catamenial discharge.

He relates the following cases in illustration of his remarks :—

Mrs. E——, who had borne five children, had never hitherto had any stoppage of the menstrual function, except when pregnant. About ten months after the birth of her last child, which was at that time weaned, she missed a period, and naturally concluded that she was again *enceinte :* this opinion was confirmed by the second period also passing without any catamenial appearance. All the usual general symptoms of pregnancy occurred in succession, but, to her great surprise, she did not quicken as usual at the fourth month, and this occurrence did not take place until the supposed seventh month of her pregnancy. The infant was born exactly twelve calendar months after the last appearance of the menstrual function.

In this case there was evidently an accidental stoppage of the catamenia for three months, at which period conception took place. The apparently late period at which the movements of the fœtus were perceived, but which, in reality, was the usual one at four months, corroborates the above fact.

Mrs. C—— had all the usual symptoms of early pregnancy in May, with total suppression of the catamenia. In this case, also, much surprise was felt that no fœtal movements were perceived until December, and the lady was not delivered till May 20th.

The two cases adduced by Mr. Atlee, in the *American Journal of Medical Science,* as proving a twelvemonth's pregnancy, are to be explained in a similar manner. In one of these cases, the last appearance of the catamenia took place on August 6th, 1832, movements were felt (?) December 25th, but the patient was not delivered until August 13th, 1833 (372 days). In the second case, the last cessation occurred on March 22, 1832, quickening took place (?) on August 5th, and parturition on March 22nd, 1833 (365 days). It is added, that the movements of the fœtus were felt daily after the period of quickening, in both instances.

Dr. Reid has known several instances in which the catamenial appearance had not occurred for many months, and yet impregnation took place. In the Northern Dispensary, in May 1846, a very respectable woman applied for a lying-in letter, she then being advanced to the seventh month of pregnancy. She assured Dr. Reid that she had not had any menstrual appearance for the two previous years ; *i. e.,* since the birth of her last child, which had been weaned for more than a year. In another case, there had been no catamenial appearance for the last six years, during which period the patient had been either pregnant or suckling. Some women even appear to conceive more readily, when there is any accidental stoppage of the menstrual function. A lady who had been married some months without becoming pregnant, was alarmed, during the night, whilst the catamenia were on her, by a cry of fire. She ran out of the house, and remained standing with naked feet on a damp lawn, until the fire had subsided. The catamenia were suddenly checked ; this occurrence was regarded as the natural consequence of the cold, and was for some time treated as a simple case of amenorrhœa. It proved, however, that she must have become pregnant immediately after the accidental stoppage from cold, and the date of her confinement corroborated the fact. Two other similar instances have come under Dr. Reid's notice, in which pregnancy speedily followed an accidental and sudden check of the menstrual discharge by cold, although in both cases no pregnancy had occurred previously for some years. Zacchias states, that he attended a lady who was in general very regular as to her monthly periods, but who never became pregnant until she had passed three or four periods previously. In some rare exceptions a monthly uterine discharge has occurred *only* when the female was pregnant.

The following table is the result of 500 cases, in which the exact number of days intervening between the last day of menstruation and that of parturition is shewn. With the exception of about fifty, they were private cases, in which the data were most correctly kept ; and the others were selected

from upwards of 1000 hospital and dispensary cases, presenting an equal certainty as to date, in females superior to the usual class of hospital patients.

Total, 500 cases.

In the case which occurred 314 days after the cessation of the catamenia, quickening did not happen until the sixth month; proving, in Dr. Reid's opinion, that conception had taken place later than had been thought. Had minute investigation been made, at an early period, into the remaining five cases, which went beyond the forty-fourth week, it is most likely that some similar facts might have been observed. The above table agrees with that of Dr. Merriman (114 cases) in showing that the greatest proportion of women complete the period of gestation in the fortieth week after the cessation of the catamenia, and a very considerable number in the forty-first week. In Dr. Murphy's table of 182 cases, the numbers born in the thirty-ninth and fortieth weeks were about equal, being twenty-four and twenty-five, whilst the greatest proportion (thirty-two) were in the forty-first week, and twenty-five in the forty-second week—equal to those in the fortieth. In Dr. Reid's tables the 282nd day was that on which the largest actual proportion of the patients were delivered; but the numbers from the 274th to the 282nd day run so near to each other that we must rather take that as the average period. If we allow of a range of from two to six days after menstruation, as elapsing probably before conception takes place, it will then appear that about the thirty-ninth week after impregnation is more probably the ordinary duration of pregnancy; and this will coincide with the results of the table taken from cases of single coïtus. [Abridged from *Lancet*, July 13, 1850.]

CASE OF "SCARLATINOID RASH" OCCURRING AFTER DELIVERY. DID AIR ENTER THE UTERINE VEINS?

Mr. Edward L. Falloon, of Liverpool, relates the following very interesting case in the *Medical Times* of January 18th, 1851. We agree with the author in thinking, that the red, or "Scarlatinoid Rash," which he saw, was in no way connected with the entrance of air into the circulation by the uterine veins. We are in some difficulty, however, as to the proper explanation of the case. Mr. Falloon writes as follows:—

"I was called, Nov. 20, at 1 o'clock, A.M., to attend Mrs. A., aged 26, with her second child. She had been complaining since 11 P.M.; pains increased;

head presenting, and pressing much on the linea of the os pubis, where she referred all her pain. At 2 o'clock, sudden fainting came on, with deadly pallor and cold extremities. On her rallying from this, by brandy, open windows, etc., the pains brisked up, and the uterus kept dilating, but was interrupted frequently by the faintness, which kept recurring without any external hæmorrhage, till 3 o'clock, when she had a fearful rigor. She rallied again, and became less faint, but complained loudly, and begged for chloroform, which I was ultimately obliged to give her, with great benefit, till her child was born at 5 o'clock A.M., without any unusual detention in the vulva, but *dead*. Immediately on its exit, the placenta followed, accompanied by an enormous clot, as large as, if not larger than the placenta ; the subsequent hæmorrhage was not excessive, but the faintness was extreme ; nevertheless the uterus contracted well. The shock of her child's death, added to her exhaustion, made her case very critical for some time (she had lost her first child from erysipelas) ; she looked blanched and anæmic to a high degree, but gradually improved. On the third day I was not a little alarmed and surprised to find her covered by a scarlatinoid rash, and the more so on being assured by her mother, then present, that she had had both scarlatina and measles. I had not met with this symptom before, and it was the more unaccountable from being unaccompanied by any appreciable fever ; pulse 96. I ordered a mild alterative and cooling aperient, and left very uneasy. On returning to my study, I happened to take up the *London Journal of Medicine* for October, and read that highly interesting and scientific article by Dr. Cormack, on 'The Entrance of Air into the Uterine Veins,' wherein he alludes to some cases occurring in the practice of Dr. Simpson, in which the same rash appeared three days after delivery, but *all* followed by death ; this made the matter more anxious for me by many degrees. Visiting early next morning, I found the patient improved ; the rash still out, but *paler ;* no febrile symptoms. I ordered a more generous diet, and it continued to disappear daily ; and she ultimately did well, and is now able to appear at her dinner-table, little more than a month since her confinement.

"It is evident this was a case of hæmorrhage in utero, prior to the rupture of the membranes, owing to detachment of the placenta, and the rigor. I suppose the evidence of the child's death ; but I am not in possession of any facts that throw light on the cause of this detachment, except that she had felt debilitated of late from a continuous attack of influenza.

"I am induced to publish this case by a remark I find in the ingenious article by Dr. Cormack, above alluded to, where he says, 'he notices his cases, in the hope that others will, when opportunities occur, make and record their observations.' I also refer to this phenomenon (the scarlatinoid rash) more with a view of adding a case to those already on record, than of proposing any theory regarding it. While I say this, I am not disposed to accept any of the theories at present propounded as at all satisfactorily accounting for this appearance ; nor do I acknowledge any analogy, so far as I am able to judge, between the 'reddish tinge' of Dr. Warren and the 'scarlatinoid rash' of Dr. Simpson ; the former appearing immediately after the evident entrance of air into the circulation, while the latter did not appear until two or three days after the shock of parturition, without any allusion to air having entered the uterine orifices. In my case, I think it is clear that no air entered ; the fainting commenced long before the membranes were ruptured, and faintness only remained after the birth of child and placenta ; besides, I had recourse to such mechanical support as made its entrance almost impossible. Nor do I see any analogy between a continuous, general, and gradually disappearing rash, as above stated, and the 'fitful suffusion of the face with a delicate blush, superseded quickly by extreme pallor.' To this latter I think Dr. Cormack's theory of 'capillary relaxation' admirably applies ; but, with all deference to such high authority, it does not satisfactorily account to my own mind for the former red

hue. If I might venture a theory on the subject myself, I would remark that I believe it to be connected with such a state of body as exists in low adynamic fever, or pure typhus, where there is a general lack of vital tone, depressed organic nervous system, and deteriorated circulating medium ; all which were evident in Mrs. A's. case. The rash disappeared on adopting a generous diet and mildly tonic plan ; in a word, it appeared analogous to petechiæ or purpura."

M. GUBLER ON ABSCESS OF THE UTERINE APPENDAGES, FOLLOWING THE COURSE OF THE ROUND LIGAMENT.

The *Union Médicale* for November 12th, 14th, and 16th, contains an interesting paper by M. Gubler, in which he relates several cases, in proof of the opinion advanced by Velpeau and Marchal de Calvi, that, in cases of suppuration in the broad ligament of the uterus, the pus may follow the course of the round ligament, and appear at the inguinal canal.

Case I. G., aged 29, primipara, was admitted into the Charity Hospital on 9th July 1846. At the ninth month of pregnancy, she had felt gradually increasing pain in the right side of the hypogastrium. Delivery was favourably accomplished ; but the pain afterwards increased, and a fulness was perceived in the right groin, which became the seat of pricking and darting pains. On July 10th, there was no fever ; the only additional symptom was a slight impediment to micturition. On examination, a swelling was discovered in the situation of the orifice of the inguinal canal. There was no change of colour in the skin ; the percussion-sound was dull, and there was evident fluctuation. The swelling could be felt along the inguinal canal, becoming more and more deep, and disappearing at a point nearer to the anterior superior spine of the ilium than to the spine of the os pubis. In the abdomen, it was much enlarged, so that, on feeling it through the relaxed abdominal walls, its boundary could be easily determined. The projection and tension of the external tumour was increased on coughing ; and the same effect was produced by pressing on the intra-abdominal portion of the tumour, or even on the inguinal prolongation. On the other hand, the size of the external projection could be temporarily greatly reduced, by pressure in the opposite direction. On the next day, the external tumour having attained the size of an egg, an incision was made, from which a large quantity of healthy inodorous pus escaped ; and a linseed-meal poultice was applied. On the 18th, the patient quitted the hospital convalescent.

M. Gubler admits that, in this case, there is some doubt whether there had been an opening from an abdominal abscess through the posterior wall of the canal, or whether the pus followed throughout the course of the round ligament.

Case II. D. L., aged 26, was admitted into hospital on 6th July, 1848. She had been delivered of her fourth child on the 15th of May. On the third day, she complained of colic ; and, after this left her, there was still pain in the loins, produced by the slightest movement. About the 12th of June, she felt a painful tension, and afterwards shooting pain, in the right side of the hypogastrium. She had ten leeches and a poultice applied, and kept her bed. Twelve days after, having found no improvement, she entered the hospital. On July 7th, there was found, towards the left iliac fossa, a rounded swelling, entirely distinct from the abdominal wall, and very painful on pressure. M. Cazeaux examined the uterus, and found nothing morbid in this organ. Febrile symptoms being prominent, M. Rayer had her bled from the arm, and a poultice applied over the abdomen. The patient appeared to go on well for some days, when the pain became more severe, and a flying blister was applied over the left side of the hypogastric region : this did not, however, diminish the pain, and the tumour went on increasing. The fever having increased, she was again bled ; and this produced a notable

alleviation of the pain. On August 8, in consequence of an increase in the size of the tumour and of the pain, six leeches were applied above the flexure at the groin. No appreciable benefit resulted; and the following was her condition on August 15th.

The internal side of the left iliac fossa was occupied by a painful and resisting tumour, which reached nearly to the level of the anterior superior spine of the ilium, and extended towards the pelvis, where it seemed to be connected with the body of the uterus. Its upper part was felt, through the abdominal wall, to be rounded. The skin had undergone no change of colour; there was no œdematous puffiness, nor superficial tenderness; but sharp pain was elicited by a little firmer pressure. There were also darting pains towards the external genital region. On examination *per vaginam*, the body of the uterus was found enlarged on the left side, with diminished mobility, and puffiness of the cellular tissue. On the following days, the tumour projected more in the groin, and was the seat of deep fluctuation. It went on extending along the groin, and at length reached the external opening of the inguinal canal. The skin then assumed a rose-coloured tint, and the fluctuation became superficial. On the 28th August, the abscess was opened; and the direction of the purulent collection was ascertained by a sound, which passed upwards and outwards, as well as gradually deeper. The patient after this went on well, and was discharged cured on the 30th September. There could only be felt, as in the preceding case, a hard cord along the inguinal canal.

Case III. E. L., aged 23, was admitted, on the 31st December, into the Hôpital Necker, under M. Trousseau. She had been recently delivered of her first child. She entered the hospital in consequence of constipation, and severe pains accompanying each stool, and continuing for half an hour after. She was found to have two superficial fissures in the mucous membrane at the back of the anus. M. Trousseau prescribed rhatany enemata, from which she received benefit. She was then attacked with gradually increasing pains in the left side of the hypogastric region. On palpation through the abdominal walls, a tumour was felt, in the situation of the left ovary. The patient suffered much pain during this examination, which was, however, conducted with great care. Nothing was discovered on examination *per vaginam*. There was a quick and full pulse, and heat of skin. In spite of leeches, poultices, and mercurial ointment, the intra-pelvic tumour slowly increased, appearing on some days very tense and painful, with strong reaction, and at other times remaining stationary, with diminution of the febrile symptoms. These exacerbations and remissions occurred three or four times; and the swelling gradually reached the anterior abdominal wall, towards the end of January 1847. When the abscess pointed, it was opened, and 200 grammes (about ʒviss.) of fetid phlegmonous pus escaped. The flow of pus was affected by the respiratory movements. The patient was attacked with diarrhœa and hectic, which much reduced her; and she died on the 7th March, after having suffered for a week from choleriform symptoms—cyanosis, rice-water stools, cold breath, and vomiting.

Post-mortem Examination, thirty-eight hours after death. The inguinal abscess was ascertained to have its opening between the pillars of the external inguinal ring. The inguinal canal was traversed by a blackish cord, dissected out in nearly its whole extent, and evidently formed by the round ligament and the vessels, which had resisted the suppurative process. The walls of the canal were also coloured; and it contained a quantity of greenish pus. The inferior border of the internal oblique and transversalis muscles, which bound the canal superiorly, were also dissected out for a small extent, from the internal orifice, towards the posterior superior spine of the ilium. The fistulous passage, having reached the anterior wing of the broad ligament, became gradually narrower, and contained cellular filaments, which increased in quantity as its situation became deeper. It finally ended at the ovary, at

the level of a grey point, with an ulcerated centre, and softened edges, which corresponded with a purulent cyst as large as a small hazel-nut. In the left ovary, also, two additional cysts, of about the same size as the other, were found, which opened into each other so as to form a single bilocular cavity. They were all lined with a white false membrane, outside which there was a layer of blackish-grey tissue ; and beyond this was the healthy stroma of the ovary. The ovary was adherent to the Fallopian tube. The uterus was bound down towards the left side by shortening of the broad ligament ; its interior was greyish, and lined by a membrane of slight consistence. There was no false membrane in the peritoneum, and only a few drops of fluid.

The matter contained in the ovaries, and in the fistulous passage, was white and opaque, perfectly resembling very thick milk of lime. Under the microscope, it appeared as a transparent colourless liquid, holding in suspension very small strongly refractive granules, which, when isolated, exhibited Brownian movements. They were, however, often collected either into bodies resembling granular corpuscles, or into larger masses. There were also some pieces of a transparent colourless substance, probably fatty matter ; while the granules were probably inorganic, the result of the transformation of pus.

Remarks. M. Gubler has observed the phenomena which he describes only in puerperal women ; and it is in these that inflammation of the broad ligament is most frequent. In all three cases, suppuration in the ovary appeared to be the point of departure : the affection was always confined to one side. These cases present some particular symptoms, beyond those common to intra-pelvic phlegmonous tumours. First, there is an ill-defined deep projection, at the level of the abdominal orifice of the inguinal canal, gradually becoming more superficial, as it extends in the direction of the canal. At the same time, fluctuation becomes more distinct. At last the abscess points at the external opening. The whole abscess thus resembles a wallet ; there is an enlarged portion externally and internally (the latter being much the largest), and an intermediate neck, a sort of inter-parietal isthmus. The large size of the internal pouch explains the quantity of pus which flows, and the effect produced on the flow by respiration.

After operating, it is easy to pass a probe along the course of the abscess in the inguinal canal. It is at the external abdominal ring that the redness of the skin is most marked ; and it is there that the abscess must be opened, which should be done as soon as fluctuation is evident, so as to avoid the occurrence of greater mischief in the interior of the abdomen, or in its walls. The incision should be parallel with the inguinal fold, so as to avoid wounding the arteries which accompany the sub-pubic ligament, or which arise from the external pubic arteries, and generally follow that direction.

The pus is always phlegmonous and of good consistence : in one case only it had a disagreeable odour. Its quantity is very considerable for the first days after the abscess has been opened, but gradually diminishes, and, in favourable cases, soon disappears. In one case, the wound was cicatrised on the sixth day ; in the second, the cure was only obtained in a month ; in the third, the purulent exudation was much diminished two months after the operation, when the patient was carried off by an attack of sporadic, or rather symptomatic cholera. After recovery, there remains an engorged hard cord, following the course of the inguinal canal.

The impulse given by coughing would cause these cases to resemble hernia ; but the fluctuation and dulness on percussion furnish a means of diagnosis.

M. Gubler recommends the application of blisters at the situation of the external abdominal ring, to hasten the pointing of the abscess in this situation. The prognosis in these cases is favourable.

PSYCHOLOGY.

DR. COLDSTREAM ON THE ATTEMPTS RECENTLY MADE TO IMPROVE BY EDUCATION THE PHYSICAL AND MORAL CONDITION OF THE FATUOUS.

Until lately, all children affected with congenital idiocy were regarded as incurable. It appears, however, from experiments recently made in France, Switzerland, America, and England, that one-third of the children subjected to appropriate treatment have been in a few years so greatly improved, both in mind and body, as to be capable of conducting themselves with propriety, and taking part in the ordinary business of life.

Three years ago, an asylum for idiots was established at Highgate, near London. The popularity and necessity of this institution are alike proved by the fact, that in 1849 there were one hundred and seventy candidates for fifteen vacancies ; and it was forthwith resolved to erect large additional accommodation. A similar institution was founded at Bath, in 1846. So long ago as 1828, M. Ferrus, chief physician of the Asylum of the Bicêtre, Paris, organised a school for his idiotic patients, and caused them to be taught habits of order and industry, and to be instructed in reading, writing, arithmetic, and gymnastics ; and latterly, much attention has been devoted to the means likely to rouse and invigorate their dormant faculties. These means, as stated by Dr. Conolly, are simple, viz., suitable space, and local arrangements adapted to the conservation of the health and safety of the pupils, and to the establishment of cleanly habits,—to presenting them with objects for the exercise of their faculties of sense, motion, and intellect,—and to the promotion of good feelings, and of a cheerful active disposition.[1] Schools for the insane have also been successfully established in the Lancaster and Surrey County Asylums, and also at Hanwell.

Even cretinism (which must be regarded as idiocy in its most intense degree) has been successfully treated, within the last ten years, at the retreat on the Abendberg, in Switzerland, by the benevolent Dr. Guggenbühl ; and his example has been followed in Wurtemberg and Sardinia. Attention has also been strongly directed to the subject in the state of Massachusetts. Private schools for idiot children have been opened at Bendorf, not far from Coblentz, on the Rhine (by Dr. Erlenmeyer) ; and at Barre, in the state of Massachusetts. At the late meeting of the British Association in Edinburgh, it was agreed to memorialise the government in favour of a national survey, to determine the extent to which congenital idiocy exists throughout the kingdom at large, and the causes of its prevalence in particular districts. But we cannot admit that it is expedient to await the result of such a survey, though important, before making any effort to give some of our poor imbeciles the benefit of the knowledge we already possess.

The reports from the institutions already in operation are highly gratifying. At Highgate—"There is now order, obedience to authority, classification, improvement, and cheerful occupation. Every hour has its duties, and these duties are steadily fulfilled. They are, essentially, not only an improving, but a happy family. And all this is secured without the aid of correction or coercion. The principle which rules the house is love." The report from Bath is equally satisfactory. "The pupils are instructed, as their capabilities permit, in reading, writing, arithmetic, and geography ; and their acquaintance with external objects is extended and improved. Religious knowledge and moral culture are directly or indirectly kept in view in every pursuit. Corporal punishment is not permitted."

"The pupils in the school in Massachusetts, although only a year in train-

[1] Brit. and For. Med. Rev. vol. xix, p. 295.

ing,[1] had improved in personal appearance and habits, in general health, and in vigour and activity of body. Some of them could control their own appetites in a considerable degree; they sat at table with their teachers, and fed themselves decently. Almost all of them had improved in understanding, and in the use of speech. Some of them had made considerable progress in the knowledge of language; they could select words printed on slips of paper, and a few could read simple sentences. They had gained a knowledge of many objects, their names, colours, forms, dimensions, etc. "And thus," the intelligent reporter concludes, "it has been demonstrated, that idiots are capable of improvement, and they can be raised from a state of low degradation to a higher condition. How far they can be elevated, and to what extent they may be educated, can only be shewn by the experience of the future." [Abridged from *Edinburgh Monthly Journal of Medical Science*, November 1850.]

MATERIA MEDICA AND PHARMACY.

CHLOROFORM AND SULPHURIC ETHER.

Dr. J. D. Gross (*Transactions of the American Med. Ass.*) makes the following remarks. "In several of my cases, transient opisthotonos appeared to have been produced by the inhalation of chloroform. This phenomenon was strikingly displayed in a young gentleman of Covington, Ky., to whose hip I applied the actual cautery on account of coxalgia. While under the influence of chloroform, which he inhaled rather badly, his head was forcibly thrown backwards, and the body forwards, precisely as in opisthotonos. The effect did not last longer than fifteen or twenty seconds. No stiffness of the jaws was noticed. On two occasions, while performing the operation of lithotomy, the patients were affected with the most violent priapism, which, however, subsided, in each case, in less than half a minute. The ages of the patients were, respectively, four and twenty-two years. I may remark here that I never witnessed a similar result in any of my stone cases in which chloroform was not administered.

"Since I have commenced the use of chloroform, I have abandoned that of sulphuric ether altogether, being persuaded, from ample experience, that the former is, in every respect, preferable. It produces the desired effect in a much shorter time, causes less excitement of the brain, is more persistent in its action, and is more easily inhaled. In a word, I have every confidence in its efficacy and safety, and could hardly imagine a more desirable anæsthetic agent.

"Finally, my rule always is to bring the system gradually, not rapidly, under the influence of chloroform; an object which is usually attainable in thirty or forty seconds, provided the patient gives his thorough cooperation, and does not embarrass us by his obstinacy or timidity."

UNCERTAIN STRENGTH OF LONDON TINCTURE OF OPIUM.

Mr. A. Allchin has called attention to this subject. Tincture of opium, properly prepared according to the *London Pharmacopœia*, contains one grain of opium in nineteen minims. In seven specimens obtained from seven different London drug-shops, the strength varied from 19, 20, 21, and 22, to 26 and 28 minims, as the equivalent of one grain of opium. Perhaps these serious variations may arise from moist opium being used in place of the dry—from avoirdupois being used in place of troy weight—and also from the great difference which exists between different kinds and supplies of opium as obtained in the market. By drying, opium loses about twenty per cent.; and it is obvious that for this, allowance should be made when the moist drug is used.

[1] Second Report to the Senate of Massachusetts, on Training and Teaching Idiots, by S. Howe, M.D. 1850.

PRACTICAL REMARKS UPON IPECACUANHA, WITH A FORMULA FOR THE SYRUP.

By Edward Jenner Coxe, M.D.: New Orleans.

The value and efficacy of ipecacuanha, as an emetic or expectorant in many affections of the respiratory organs, more particularly of children, are too generally conceded and acted upon to require an extended notice.

In dysentery, ipecacuanha has been, and continues to be, much used. By Mosely, who held it in high repute, ipecacuanha was given in doses of half a drachm to two scruples; and by the late Professor B. S. Barton, it was regarded as almost a specific, particularly in cases of a typhoid character. In chronic diarrhœa, small doses of the powder, repeated several times a day, either alone, or preferably in conjunction with opium or Dover's powder, will be found of great value, and frequently, with strict attention to a proper regimen, will succeed in curing many most unpromising cases. In these last cases, when dependent upon, or connected with, derangement of the biliary secretion, additional power will be given to the above doses, by uniting with them two or three grains of blue mass, to be repeated every night for three or four nights, and subsequently every third or fourth night, as long as may be deemed requisite or advisable for the individual cases.

In hæmorrhage from the lungs or uterus, small doses of ipecacuanha, combined with sugar of lead and opium, are used with decided benefit. In hæmorrhage from the stomach, large doses of ipecacuanha have been strongly recommended, more particularly by Dr. Condie, who has published some valuable practical remarks upon the subject.

In the early stages of the bowel affections of children, no less than in adults, an emetic of ipecacuanha will often succeed in arresting the progress of the disease, and rarely fail to prove beneficial.

By combining from one-fourth to half a grain of ipecacuanha, with a minute portion of opium, and two or three grains of blue mass, the alterative properties of this last are materially enhanced. This method will be found of great benefit in most of the mild cases of biliary and bowel derangement so prevalent in this region, at different seasons of the year.

With the exception of that sudden and often fatal disease, croup or hives, there are perhaps none of the pectoral diseases of children, in which the syrup of ipecacuanha may not be resorted to with advantage; but in croup, no little experience, and an almost uniform success in its treatment, authorize the confident belief, that we possess no one remedy, or combination of remedies, comparable, or equal to the well-known Coxe's Hive Syrup, provided it be properly prepared. Dr. Good has remarked, that the ipecacuans concur in operating very generally upon the skin, at the same time that they excite the stomach, increasing, in a slight degree, the discharge of mucus from the lungs, and adding a little to the peristaltic motion of the bowels, while the antimonials act more violently upon the stomach, bowels, and skin, but less upon the mucous secernments.

Finding the process, for the syrup, recommended in the United States Dispensatory, attended with unnecessary trouble, and uncertain as to uniformity, I adopted, after many trials, the following formula,

R.—Ipecacuan. Rad. contus.	ʒ iv,
Aquæ	O. ij,
Sp. Vin. Rect.	ʒ x,
Sacch. Alb.	lbs. iij.

Macerate the bruised ipecacuanha in one pint of boiling water for twelve hours, then add the remainder of the water and alcohol, and continue the maceration for five or six days. Place the whole in a small displacement apparatus, returning the fluid that passes until it becomes perfectly clear, and then continue to pour a small quantity of water occasionally upon the surface, until two pints and ten ounces by measure shall have passed. Now add the

sugar, and with a gentle heat, evaporate until the syrup shall be of a proper consistence, readily ascertained by occasionally taking out a small portion and allowing it to cool. When of a proper consistence, pass it through a small quantity of fine tow placed in the tube of a funnel, to render the syrup clear and transparent. Three pints and ten ounces of syrup is the quantity obtained. It is, in strength, nearly double of that prepared by the usual formula; and this I consider an additional recommendation. [From the *Western Lancet.*]

HYGIENICS.

WHAT DISEASES OF THE SKIN ARE INCOMPATIBLE WITH LACTATION?

This is a practical question of the highest interest; and its solution has hitherto been far from satisfactory. The following is a summary of a memoir which M. Cazenave has published, on the subject, in the *Annales des Maladies de la Peau* for October and November 1850.

There is a great number of skin-diseases which, speaking absolutely, are not incompatible with lactation. Such are the non-specific eruptions, in the acute stage; erythema, herpes, eczema, pemphigus, impetigo, ecthyma, having, in this stage, no other force than that of an accidental transitory inflammation, and exercising no appreciable influence either on the lacteal secretion, or on the health of the infant. Considered relatively, some of these diseases may, under certain circumstances, have peculiar effects. Thus acute eczema, if intense and general, may have the effect, through its general influence on secretion, of diminishing the quantity of milk. Impetigo, denoting a morbid exaggeration of the lymphatic temperament, may also be incompatible with lactation; and so also may lichen and ecthyma. But, setting aside certain relative peculiarities, and certain individual circumstances, or organic relations between the nurse and the infant, which impress on these eruptions a character of relative severity, of which the value can only be ascertained by examining each case by itself, M. Cazenave thinks that, in general, most of these eruptions, when in the acute stage, cannot be considered as a reason for rejecting a woman as a wet-nurse, and still less for discontinuing the suckling of an infant by one in whom any of them has appeared during lactation.

As to these affections in the chronic stage, and as to those various forms of skin-diseases which are confounded under the name of *dartres*, M. Cazenave thinks that there is a large number which are compatible with the function of lactation, and of which the presence, either in the mother, or in the nurse, should not be considered a source of danger to the infant, nor a reason for changing its food. Any influence which these may, under certain conditions, exert on the infant, is only relative.

The cutaneous diseases which have a negative absolute value in the choice of a nurse, or which ought to become an obstacle to the continuation of lactation, belong to several categories. Eczema, impetigo, or lichen, may become incompatible with lactation, when in the chronic stage, and when their extent and intensity are more considerable than usual. But there are some diseases of the skin which of themselves, independently of all circumstances of duration or intensity, produce in general, though in different degrees, a complete change in the economy. And this change, although accidental and possibly only transient, is such as to impart to these eruptions, even in the acute state, an absolute value, as contra-indicatory of lactation. Such are chronic ecthyma, which always denotes a cachectic state of the constitution; rupia, pemphigus and purpura, which likewise reveal a deterioration of the system.

There are, further, some diseases of the skin, which are very important in

the point of view which we are now considering, and which are characterised by degeneration of the tissues, and by their tendency to destroy the affected parts; such as the two forms of elephantiasis, molluscum, lupus, keloid, etc.

The contagious skin-diseases (itch and herpes tonsurans) cannot have any influence on lactation; but it is otherwise with favus, which is one of the most incompatible. There remains but one form of skin-disease—the syphilitic—which is directly transmissible by suckling, and consequently is the most incompatible of all.

Recapitulation. It is no longer allowable, in making choice of a nurse, to proscribe, in a general manner, the diseases of the skin known under the name of *dartres*. With regard to lactation, skin-diseases have different values, not only according to their nature, but also by reason of certain accidental conditions of individuality, extent, intensity, etc. The syphilitic affections alone should be excluded as virulent. Several cutaneous affections have a negative absolute value, as producing a generally severe modification of the organism: these are precisely the diseases farthest removed from those called *dartres*, and which do not properly constitute eruptions. The eruptions, properly so-called (*dartres*), are generally compatible with lactation. Some may accidentally lose this quality, by being of unusual intensity, or by transmitting a deterioration of the economy; but they are few in number. The eruptions which, in their nature and local conditions, are perfectly compatible with lactation, may cease to be so relatively, in consequence of certain peculiar relations between the nurse and the infant. [*Bulletin Général de Thérapeutique*, 15 December 1850.]

DISEASES ATTACKING PERSONS EMPLOYED IN THE MANUFACTURE OF SULPHATE OF QUININE.

At the meeting of the Academy of Sciences in Paris, on the 5th October, a memoir by M. Chevallier was read, on the health of the men employed in the preparation of sulphate of quinine, and on the means of preventing the diseases to which they are subject. The manufacture of sulphate of quinine has been carried on in France for thirty years, and has produced certain affections, which have not hitherto been studied. M. Chevallier's researches have led him to the following conclusions.

1. The workmen, employed in the manufacture of sulphate of quinine, are liable to be attacked by a cutaneous disease, which compels them to suspend their work for a fortnight, a month, or even more. 2. There are some workmen who cannot continue the work, and are obliged to quit the manufactories where they are employed. 3. M. Zimmer, manufacturer of sulphate of quinine at Frankfort, has observed that the men employed in the pulverisation of quinine in his manufactory, were attacked by a peculiar fever, which he calls cinchona fever (*china fieber*). 4. This fever has not been observed in France. 5. No means have, as yet, been discovered to prevent the cutaneous disease which affects those employed in the manufacture of sulphate of quinine. 6. This cutaneous disease attacks not only the men employed in different parts of the works, but also sometimes persons who are exposed to the emanations from the manufactories. 7. It attacks those workmen who are of sober habits, as well as the intemperate. 8. The existence of predisposing causes in the workmen is not demonstrated: but many believe that such exist.

For the prevention of the diseases referred to, M. Chevallier recommends that the manufactory should be in a well-ventilated situation, and that the workmen should expose as little as possible of the cutaneous surface either to the aqueous, or the alcoholic decoctions. He further suggests that it might be possible to destroy the emanations by the use of chlorine fumigations. [*L'Union Médicale*, Oct. 10, 1850.]

THE HOSPITALS OF LONDON. No. II.

BY DR. CORMACK AND DR. SEMPLE, ASSISTED BY NUMEROUS REPORTERS.

THE VITAL STATISTICS OF HOSPITALS.

Dr. Webster has recently directed the attention of the profession to this subject, by his paper in this Journal, which appeared in December last; and various criticisms and suggestions have likewise been elicited by that communication. The commencement of a new department in the London Journal of Medicine, devoted to the "Hospitals of London", is, we may add, bringing into our possession much valuable information on the same subject. In the meantime, we think, the publication of the following letter cannot fail to be of much use in giving a proper direction to the inquiries now making, or about to be made, by ourselves and others, into the vital statistics of the London Hospitals. We thank Dr. Rees for permission to print his valuable communication.

Letter to Drs. Cormack and Semple, *from* G. Owen Rees, M.D., F.R.S., *Fellow of the Royal College of Physicians, Assistant Physician to, and Lecturer on Materia Medica at, Guy's Hospital.*

Gentlemen,—The subject of mortality in Hospitals, which has of late attracted the notice of the profession, will naturally occupy your attention. I am therefore anxious to bring before you a plan of return, which, were it generally adopted, would at once shew the fact of increased mortality in any particular hospital or hospitals, with a degree of accuracy such as I am not aware has yet been attempted. I cannot refrain from expressing regret that, while careful analysis of statistical returns supplies us with most valuable knowledge, it is still, unfortunately, too evident that this analysis is, even in the present day, occasionally neglected; and that returns, in themselves correct, are made instrumental to fallacious reasoning, and the promulgation of the grossest errors.

It will be well, perhaps, here to enumerate, in the first place, some of the causes for variation, which must affect hospital statistics, and invalidate returns referring to the total deaths per annum, in so far, at least, as they may be used *in comparing the mortality of one Hospital with another.*

1st. The mortality among physicians' cases is greater than among surgical cases; and hospitals do not contain the same proportions of these two classes of patients.

2ndly. The mortality among ophthalmic cases is scarcely any; and some of our General Hospitals (Guy's more especially) have always a certain number of ophthalmic cases in the wards.

3rdly. The mortality among obstetric cases may be regarded as probably less than that of medical cases generally; and hospitals contain this class of patients in varying proportion.

If the above statements be admitted, we ought then to place the deaths, medical, surgical, obstetric, and ophthalmic, in different categories.

Even with this arrangement, however, the number of deaths occurring during a year in each institution, and under each head, will shew us but little, if we place the *number of beds* devoted to each subject side by side with the mortality for each hospital, and for the following reason. The number of patients passing through different hospitals in any given time, bears no relation to the number of beds contained in each,—hospitals in which the *accommodation is equal* passing very *different numbers* of patients through their beds during the year. This difference is so marked, that in one case the excess, I know, amounted to more than one-third of the whole number passing through the hospital, the population of which had been the most stable.

In the table I append, you will perceive that this evil is obviated, by taking the number of patients under each heading passing through the hospitals during a year, and comparing the number with the total mortality for the same period. The derived column headed "Deaths per cent." will then give the correct comparison at a glance.

The mortality among children in General Hospitals may, I think, be safely taken at about the same as that among physicians' cases generally. Their number is not great in such institutions. It may also be well to mention, that patients will sometimes leave hospitals immediately before death, in order to die at home, either at their own desire or that of their friends. This, I believe, is not a very material point, so far as comparison is concerned, as it probably affects hospitals about equally upon the number of patients passing through them during the year. It would appear of the very greatest importance, to detect the difference in the mortality of hospitals. With correct information on this point, we can scarcely fail, not only eventually to detect the causes of evil, but we may perhaps also gain a knowledge of the *more specific influences* exercised by these causes, as they shew themselves in the various localities of the metropolis. I append the table which I would propose for these hospital returns, and have the honour to be,

Sirs, very obediently yours,

G. Owen Rees.

10, *Cork-street, Burlington-gardens,*
January 20th, 1851.

Name of Hospital.	Medical Cases.			Surgical Cases.			Obstetric Cases.			Ophthalmic Cases.		
	No. of cases in the year.	Actual Deaths.	Deaths per cent.	No. of cases in the year.	Actual Deaths.	Deaths per cent.	No. of cases in the year.	Actual Deaths.	Deaths per cent.	No. of cases in the year.	Actual Deaths.	Deaths per cent.

GUY'S HOSPITAL.

The following is the Medical Staff at Guy's; with the date of each officer's election.

Consulting Physician. Dr. Bright, *elected* 1824.

Physicians. Dr. Addison, *elected* 1824; Dr. Babington, *elected* 1838; Dr. Barlow, *elected* 1840.

Assistant Physicians. Dr. Hughes, *elected* 1840; Dr. Rees, *elected* 1843; Dr. Golding Bird, *elected* 1843.

Surgeons. Bransby B. Cooper, Esq., *elected* 1825; Edward Cock, Esq., *elected* 1838; John Hilton, Esq., *elected* 1845.

Assistant Surgeons. John Birkett, Esq., *elected* 1849; Alfred Poland, Esq., *elected* 1849.

Obstetric Physicians. Dr. Lever, *elected* 1844; Dr. Oldham, *elected* 1845.

Surgeon of the Eye Infirmary. John T. France, Esq., *elected* 1849.

Physician to the Lunatic Ward. Dr. Gull, *elected* 1847.

Resident Medical Officer. James Stocker, Esq., *elected* 1834.

Last month we gave a short account of the plan of clinical instruction in Guy's Hospital. We now subjoin some details of the general *matériel* of the school,—viz., its Museums, Library, Dissecting-room, etc.

The Museums of Human and Comparative Anatomy are on a scale which entitles them to rank among the first of our national collections. The late treasurer, Mr. Harrison, under whose auspices they arose, and have reached their present large development, has conferred a lasting obligation on our profession by the munificent manner in which he carried out his designs for the advancement of medical education ; and we may venture to say that, in the means of teaching, Guy's Hospital School is not second to any institution in this country. The present treasurer, Mr. Dobrée, has, since he has been at the head of affairs, done much towards the furtherance of the labours of his predecessor, by affording a more commodious building for the Comparative Museum, and by the erection of a new Dissecting-room.

The *Museum of Human Anatomy* is divided into an anatomical and a pathological department ; both of which are replete with numerous and illustrative examples, under the several subordinate divisions.

The anatomical department contains nearly two thousand different preparations of the organs and tissues. The principal contributors have been Dr. Hodgkin (who laboured at it for many years, and to whose talent and industry it is much indebted), Sir Astley Cooper, Mr. Key, Mr. Cock, and Mr. Hilton ; and, for the female organs of generation, Dr. Oldham.

This division of the museum deserves especial mention, from its containing a series of models of the different regions and organs, which stand unrivalled as works of art, and present one of the most complete and most minute representations of the body in existence. They have been executed within the walls of the institution, by Mr. Towne, from dissections made by Mr. Hilton, the lecturer on anatomy, who has been assisted during the last three years by Mr. Callaway. We would premise our remarks upon them by observing, that their intention is not to supersede the necessity for dissection by the student himself, as some have misapprehended. Nor indeed have they that effect ; but amongst other advantages which they possess, such as presenting at a view the ordinary relation of parts, etc., many of them are from dissections more elaborate than the general skill of a student could enable him to produce, during the usual period of his studies ; and others represent complex relations of parts, which could not be arrived at without many separate dissections, and a knowledge of which the student could not in many instances obtain without this assistance from art. Although their great beauty and delicacy of finish may be appreciated by the uninstructed, yet they can be adequately prized only by the anatomist, who sees in them an actual representation of all that his utmost perseverance could effect upon the recent tissues. It is but due to the talent which is here shewn, to draw attention to this distinction, particularly as their general merit as works of art is apt to cause their intrinsic and essential worth, namely, their truthfulness, to be overlooked.

The illustrations of the anatomy of the brain deserve especial praise. Of these there are thirty, exhibiting different sections of the organ in all its details. There are also thirty-nine, shewing its development from the earliest fœtal conditions, and a unique series of the convolutions in the principal varieties of the human race. The organs of sense have also been fully illustrated, especially the ear, the complex parts of which have been developed with exquisite skill, the relative proportions being maintained, and even the character of the textures preserved. The entire distribution of the nervous system is shewn ; and we may refer to the model shewing the branches of the fifth nerve and its connexions, as a master-piece, both of dissection and of modelling. To give a description of the whole would be to write an entire work on anatomy, for the nervous, muscular, circulatory, and absorbent systems have been each fully displayed.

The pathological department is divided into twelve sections. It contains four thousand eight hundred specimens, with two thousand drawings, representing the appearances in the recent structures. The drawings are arranged in a cabinet, so as to correspond to the different sections, which are as follows. I. Diseases of bone. II. Joints, ligaments, tendons, etc. III. Vascular system : Heart, arteries and absorbents. IV. Nervous system : Skin. V. Respiratory organs. VI. Digestive organs : Liver, spleen. VII. Urinary organs : Calculi. VIII. Female generative organs. IX. Male generative organs. X. Peritoneum. XI. Utero-gestation, malformations. XII. Parasites. In each section the specimens are arranged under—1st. Deficiency ; 2nd. Excess ; 3rd. Form ; 4th. Disordered nutrition, common inflammation, etc. ; 5th. Scrofula ; 6th. Malignant disease ; 7th. Parasites ; 8th. Injury.

The contributors have been numerous ; among the principal we may name Dr. Hodgkin, Sir A. Cooper, Mr. Key, Dr. Bright, Dr. Addison, Mr. King, and Mr. Bransby Cooper. The latter has recently made a valuable addition to the calculi, and rendered them more readily available to the student, by appending sketches to the section of each stone, so that the eye is at once directed to the different layers it contains. There are in all two hundred and seventy-eight specimens ; and with each there is given a chemical analysis, made by Dr. Golding Bird or Dr. G. O. Rees, and, of late, by Mr. Cooper himself.

This department has also been greatly enriched by a numerous series of models of diseases of the skin, which may with propriety be termed *clinical illustrations*. They form a valuable and unique contribution to this division of pathology. Amongst them are many rare, and some hitherto undescribed, forms of disease. They have been selected and classified by Dr. Addison, whose attention has been directed to this object, as opportunity afforded, during the last quarter of a century, and whose labours herein have proved him a worthy successor of Willan and Bateman, whose pupil he formerly was. They have been executed by Mr. Towne, who has here, as elsewhere, mastered the difficulties of his subject, and given a result which is truly wonderful.

Besides the preparations and drawings above named, there are 1,300 diagrams (or rather enlarged drawings), for the use of the lecturers on anatomy and physiology, surgery, and midwifery ; and 660 for comparative anatomy. There are also 330 pathological casts in plaster, shewing various deformities, dislocations, herniæ, etc.

The *Museum of Comparative Anatomy* occupies the left wing of the museum. It contains 2,550 specimens. The ground floor is principally occupied by skeletons, arranged in the Cuvierian order, from man downwards. The series is very complete, and contains many rare and valuable examples. In the galleries, the preparations of the normal organs are disposed in physiological sections, each of which is well illustrated : for example, of the nervous system there are nearly sixty dissections from the principal classes. The chief contributors have been Sir A. Cooper, Mr. Thomas Bell, Mr. Morgan, Mr. King, and the present lecturer on physiology, Dr. Gull.

The Museum of Materia Medica contains specimens of all the drugs and preparations in general use, under the different forms in which they are ordinarily met with in commerce, together with the principal adulterations. Dr. G. Bird has added a collection of the more rare *proximate principles*, which have a special interest in connexion with the recent advances in the chemistry of animal fluids. Although this department is not, from want of space, so commodiously arranged as might seem desirable, its usefulness for all practical purposes is proved by the fact, that the pupils from this school have, since 1842, obtained five exhibitions, and eight gold medals, at the University of London, on this subject. A plan for the construction of a laboratory for *practical* chemistry is under consideration, and will be carried into effect, so soon as a convenient spot for its erection can be determined upon.

The Library contains 3,224 volumes. It is supplied with three weekly, six monthly, and five quarterly journals of medicine, natural history, and philosophy ; among which are the London Journal of Medicine, also the *Archives Générales de Médecine*, *Annales des Sciences Médicales*, *Müller's Archiv*, *The Philosophical and Linnean Transactions*, *Taylor's Scientific Memoirs*, etc. etc. It is open to students daily, from nine to five, without additional fees. As during the day there is but little leisure for reading, each student is permitted to take home one volume, which must be returned by ten o'clock the following morning, under penalty of a small fine, or loss of privilege for a week. It is the duty of the librarian to register the names of those who avail themselves of this privilege, together with the books taken.

The Dissecting Room is of recent construction, and has many arrangements deserving notice. The dimensions are—length forty-six feet, breadth twenty-four feet six inches, and height twenty-four feet. The ceiling is vaulted. It is lighted by a lantern, or sky-light, thirty feet by twelve feet, glazed with large sheets of rolled plate glass. The floor is of asphalte, which has the advantage of warmth, and does not imbibe moisture. The walls are lined to the height of seven feet with slabs of slate, which are for the delineation of extemporaneous diagrams. It is ventilated by twenty grated openings, ten near the floor, and ten in the ceiling, communicating with a main shaft at some distance from the building. The result is very satisfactory ; for though no means are used for disinfection, the air is kept at all times pure. There is a large private room adjoining, for the demonstrators to receive their classes in, when demonstrating the different organs ; and the washing-rooms, etc., for the convenience of students, are all that could be desired. We would recommend the dissecting-room at Guy's as a model for similar buildings.

LOCK HOSPITAL.

The following are the names of the gentlemen composing the Medical Staff of the Lock Hospital, with the dates of their election.

Consulting Physician. Dr. Sayer, *elected in* 1847.

Surgeons. E. Cutler, Esq. and Samuel Lane, Esq., *elected respectively in* 1840 *and* 1848.

Assistant-Surgeon. Henry Lee, Esq., *elected in* 1848.

The Lock Hospital, Harrow Road ; the Chapel and Asylum, Westbourne Green, are thus briefly described by Mr. Peter Cunningham, in his *Handbook of London, Past and Present* (edition 1850, p. 295) : "Supposed to be called '*Lock*' from the French *loques*, rags ; from the rags (lint) applied to wounds and sores ; so *lock* of wool, *lock* of hair. The hospital (the only one of the kind in London) was established in 1746, for the cure of females suffering from disorders contracted by a vicious course of life ; the Chapel, in 1764, as a means of income to the hospital ; and the Asylum in 1787, for the reception of penitent females recovered in the hospital. A subscription of three guineas annually entitles to one recommendation : 50*l.* as a donation, or 5*l.* 5*s.* annually, constitutes a governor. The Loke, or Lock, in Kent Street, Southwark (from which the present hospital derives its name), was a lazar-house, or 'spital for leprous people, from a very early period. There was a second betwixt Mile End and Stratford-le-Bow ; a third at Kingsland, betwixt Shoreditch and Stoke Newington ; and a fourth at Knightsbridge, near Hyde Park Corner. In one of these Locks, Bully Dawson died in 1699, aged 43. St. Giles'-in-the-Fields and St. James' Hospital in Westminster (now the Palace), were both instituted for the reception of lepers."

When the hospital was founded, in 1746, it occupied a building in Grosvenor-place. The lease having expired in 1842 ; and the ground being required for other purposes, it was removed to its present site. In the centenary report, printed in 1846, the following summary is given of the statistics of the institution. In perusing this table it is important to bear in mind "that no person is re-admitted, on any recommendation whatever, who has been discharged for irregularity, or has again received the infection" ; and

we are likewise informed in the centenary report, that "the house is almost always full, and that it is often necessary to postpone proper objects for want of room."

Patients cured—From January 1747, to 25th March 1845 ...		55,230
In-Patients cured—25th March 1845. to 25th March 1846 ...	312	
Out-Patients cured .....Ditto.....	170	
Eloped.....Ditto.....	35	
Discharged for ill-behaviour.....Ditto.....	16	
Died.....Ditto.....	1	
In-Patients—25th March 1846.....	42	
Out-Patients—Ditto	43	
	——	619
Total.....		55,849

In the report for 1850, it is stated that since the foundation of the hospital, 58,514 patients have been admitted and cured, and that during 1850, the number admitted and cured was 885.

We are astonished to observe the small amount of money which is collected. It is not only desirable that the miserable women who, sometimes from choice, but more frequently from necessity and to avoid starvation, are driven to prostitution, should have medical aid; but it is also most important, for the sake of the virtuous poor who go to general hospitals, that they should be kept separate, and afforded religious instruction and advice when under treatment. The following is the

Statement of Income and Expenditure for 1850.

Liabilities outstanding 31st December 1850, about £680.

The present beautiful edifice was commenced in 1841. In April the necessary excavations commenced; and on the 29th of May, in the same year, his Royal Highness the late Duke of Cambridge—an efficient friend of this and other metropolitan charities—laid the foundation-stone, in presence of a large and distinguished assembly. The hospital furnishes accommodation for fifty male and fifty female patients. Some idea of the enormous expense which attends the erection and furnishing of a London hospital is afforded by the following account, which we extract from the third Report of the Building Committee, of date June 4th, 1842.

The Asylum was founded in 1787, in connexion with the old Lock Hospital, by the Rev. Thomas Scott, the pious and well known Bible commentator. In 1842 it was removed to its present site ; and in 1848-49 was enlarged to its present dimensions. When first founded, the asylum received only 16 inmates ; in 1842 it was enlarged, so as to receive 20 ; and now it is capable of containing 100. Since the foundation of the asylum, 1175 female patients of the hospital have been admitted—a majority of whom have been provided with situations, restored to their friends, or otherwise comfortably settled in life. At present there are generally about 45 in the asylum.

The accounts of the asylum are kept distinct from those of the hospital. The following is the official

Statement of Income and Expenditure for 1850.

Liabilities outstanding 31st December 1850, about £175.

A system of registration has been adopted at the Lock, which, if properly carried out, may afford much valuable information. The object of this system is to present in a condensed form the aggregate result of the cases received during the year. When each case is only taken in a separate form, the knowledge to be derived generally lies buried under a mass of unattractive detail, which few have either the time or the patience to wade through. But when the principal features of the cases are extracted and arranged in a tabular form, general results are strikingly displayed, and easily understood. We sincerely wish that the plan which has thus been commenced at the Lock hospital may in future years be carried out fully and accurately ; and we cannot help thinking that the same, or a somewhat similar system, might with advantage be adopted at other hospitals, and with reference to other diseases than the venereal. The inspection of the register, to which we have been kindly afforded access, while it shews that with a very little trouble much more might be accomplished than has hitherto been done, contributes valuable information.

Out of fifty-five cases of secondary syphilitic eruption, forty-six had never taken mercury properly for the primary disease. The history of the remaining nine cases is not given. In the forty-six cases, the previous treatment of which is recorded, we find that twenty-two had taken no mercury ; fifteen had taken it for a short period only ; and three had used it irregularly. In the remaining six cases, the effect of the mercury was either very slight, or excessive.

It is a very remarkable fact (already noticed in the London Journal of Medicine, vol. for 1849, p. 801), how very seldom it happens that cases of secondary syphilis present themselves at our London hospitals, where a properly regulated and sustained course of mercury has been employed in the treatment

of the primary disease. In almost all the cases in which that medicine has been used, and secondary symptoms have followed, it becomes very easy to point out the circumstances in the treatment which have prevented its legitimate action upon the system. When used without proper care, and without its effect upon the system being properly regulated and controlled, it not only fails to cure the disease, but actually leaves the patient in a worse state than if he had taken no medicine at all. The statistics which we have been able to collect upon this subject undoubtedly shew that a worse class of symptoms follow an ill-regulated course of mercury than where the disease is left to be combated by the unaided powers of the constitution. It may therefore become a serious question with those who are unwilling or unable to devote the requisite time and attention to a mercurial course, whether they had not better abstain from the use of mercurials altogether. But, on the other hand, where the remedy has been administered with due care and attention, the testimony we have appears greatly in its favour. Our tables of secondary disease show a comparative absence of cases in which a mild but sustained course of mercury has been used for the primary affection; and we therefore conclude that did circumstances permit, mercury might be so used in the treatment of this disease, as to reduce the number of those in whom any subsequent symptoms occur, to a few exceptional cases.

REPORTS OF SOCIETIES.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Tuesday, January 14, 1851.

Samuel Solly, Esq., Vice-President, in the Chair.

Large Fibrous Tumour of Uterus. By R. R. Robinson, Esq. A tradesman's wife, aged 40, pregnant with her third child, four days before her confinement, slipped down four stairs, without feeling any inconvenience, and on the same day caught her foot against a chair, from which she felt pain in her left hip, which recurred at times subsequently. She was confined at four o'clock in the afternoon; the labour was in every respect natural. The placenta was thrown off by uterine effort in a short time; the uterus contracted well, and there was no hæmorrhage. About two hours afterwards, she was seized with cold chills, and, upon being put to bed, was sick and faint. Mr. Robinson saw her five hours and a half after her confinement, and found her in a state of complete collapse. Fearing there was internal uterine hæmorrhage, and not feeling certain about the state of the uterus, he introduced his hand, and found that organ flaccid, but free from blood. By cold and pressure, and by keeping the hand some little time in the uterus, contraction of a feeble kind was produced, and also a somewhat improved condition of the system generally. She rallied a little, but never fairly got out of collapse; she lived ten days, and died apparently from atonic peritonitis. Upon dissection, twenty-four hours after death, the intestinal convolutions were of dark colour, being smeared with blood, and were united to each other and to the uterus, by recent and easily-separable adhesions. There were three pints of dark venous blood, without coagula, in the peritonæum. The tumour was covered with peritonæum, an elongation from the uterus, and this, at the angle of reflexion, was lacerated to the extent of two inches. Mr. Robinson was of opinion that the tumour had augmented much during the growth of the uterus, and that, in consequence of being entangled with the intestines, did not move so readily when the uterus contracted, as the uterus, and thus the peritonæum, being put upon the stretch by recurrence of pain, gave way.

Cases of Ruptured Liver, Lung, etc. By Athol Johnson, Esq. The author related five cases. In four of these, death occurred either directly

from the injury to the internal organs, or from injury to the spine, at intervals varying from two or three days to three weeks. In one case, in which the patient lived for three weeks, dying then from injury to the spine, the liver, which had been extensively lacerated, was found to have nearly united. In another case there was strong reason to believe the liver had been ruptured, but the patient recovered, and of course this point could not be demonstrated. The patient, however, a little girl, was admitted into St. George's Hospital, in consequence of having been run over by a cart, which passed over her belly. She was in great pain in the abdomen ; much collapsed ; and the face was pale and exsanguined. She, however, recovered. The five cases had occurred in one year, during which the author had been house-surgeon to St. George's Hospital. The prognosis, in those cases where the injury was great, was unfavourable ; but where it was moderate, recovery might take place. In one of the cases detailed, the patient, after living three weeks, died from the spinal injury ; the liver and kidney, which had been lacerated, being found, on examination, to be nearly united. This showed the power of reparation in such cases. With respect to treatment, the author refrained from the use of brandy and stimulants, in the stage of collapse, because they would tend to the production of further hæmorrhage : the patients were to be kept quiet, and not allowed to make any exertion whatever ; the bowels were not to be disturbed by purgatives for two or three days, and full opiates were to be given. The necessity of quiet was much insisted upon, as in two of the cases detailed the patients had died suddenly, from change of posture in getting out of bed.

MISCELLANEOUS INTELLIGENCE.

Clinical Medicine and the Society of Apothecaries. We are happy to give insertion to the following correspondence between Dr. Nelson, the Professor of Clinical Medicine in Queen's College, Birmingham, and the Court of Examiners of the Society of Apothecaries.

To H. Blatch, Esq., *Secretary to the Society of Apothecaries.*

Queen's College, Birmingham, Dec. 12, 1850.

Dear Sir,—Will you oblige me by giving me some clear and settled idea on the following subject. Your Society's rules, as exhibited in the Student's Number of the *Lancet* (Sept. 28, 1850), declare very distinctly, that each student who commenced his studies on or after Oct. 1, 1849, must produce, before his examination, certificates of having attended a summer course of lectures in clinical medicine during his second year, and a winter course during his third. Physicians of hospitals, according to duty, are naturally desirous of doing all in their power for pupils ; at the same time, it must be confessed that their lectures are seldom attended by the body of clinical students. Now, this is found to be due to an existing impression, both among students, and some professors, that the certificates of such attendance, though stated as necessary in your printed rules, are not *imperative* or *essential*, but simply *formal*. I quite coincide with the important view which your board attaches to clinical instruction ; but should like to be assured, on undoubted authority, that the rules laid down in this respect are really meant to be carried out, and that the Court intend to second the efforts of clinical professors by looking as much to their certificates as to those of others. So far as I can learn, similar impressions seem to exist amongst the students of other English schools ; and therefore the board, in their accustomed zeal for improving medical education, might, perhaps, with advantage, take some means of making their sentiments decidedly understood throughout the country. The clinical professors have no pecuniary interest in this matter, as all is included in the hospital fees, and therefore, while endeavouring to excite some zeal for practical study, they only desire the real welfare of their students. That much ardour, to a certain extent,

does exist here, is proved by the fact of twelve gentlemen having put down their names, voluntarily, for examination by me; but I do think it only just to such as entertain the above impression, that the rule should be clearly understood; as, in the event of any such impression being continued, and proving erroneous, they might, at the end of their three or four years of study, and just, perhaps, as they looked forward to some immediate appointment, find themselves in a very awkward and unexpected relation to your board, such as might damage their worldly prospects through life.

I am, dear Sir, your faithful servant,

D. Nelson, M.D. Edin.,
Physician to the Queen's Hospital, and Professor of Clinical Medicine.

To Dr. D. Nelson, *Queen's College, Birmingham.*

Dear Sir,—The Court of Examiners of the Society of Apothecaries have directed me to forward to you the following reply to your letter of the 12th inst.:

That the Court of Examiners do not desire to limit, or to define the plan to be pursued by the physicians of hospitals in delivering clinical instruction to their pupils; but the Court wish that it may be distinctly understood that they consider such instruction as imperatively necessary, and that attendance upon it should be enforced in such a manner as the physicians may think expedient.

The Court, in proof of their desire to encourage a regular and definite system of clinical instruction, beg to refer to the last copy of their regulations, p. 10, wherein it is stated that a certificate of attendance upon a course of not less than seventy-five lectures on clinical medicine, delivered by a distinct professor, will be received in place of the second course upon the theory and practice of medicine.

But, as some of the schools are not yet provided with distinct professors of clinical medicine, the court at present leave the mode of clinical instruction to be arranged by the physicians; but they repeat that they consider such instruction to be *imperative* in all the schools, and that the part of the schedule appropriated to clinical lectures should be filled up only after a *bonâ fide* attendance, as in the case of the other lectures.

I remain, dear Sir, etc.,

Dec. 27, 1850. Henry Blatch.

Notwithstanding the innumerable facilities which are offered in this metropolis to the pursuit of medicine as a practical science, it is lamentable to observe the general neglect of clinical instruction on the part of both teachers and students. We fear that a systematic plan of clinical medicine is adopted at very few of our great hospitals; and we shall be rejoiced if the efforts of the Examining Boards should have the effect of bringing this important subject more fully under the notice of those, to whom are entrusted the management of the sick and the education of the students. With much zeal, and most praiseworthy energy on the part of many of the teachers, we fear, that even when clinical lectures are regularly delivered, the object and purpose of clinical teaching are too often misunderstood. It is too often the fashion to fill clinical lectures with the accounts of rare and severe operations, and with disquisitions upon the history of unusual or obscure diseases, while but little pains are taken to impress upon the minds of the students the leading features of the pathology and treatment of those common forms of disease, which will fall to the lot of every practitioner to treat in his professional career. To prepare an elaborate lecture upon one particular case of disease requires a great expenditure of time and of research, and the result, after all, may not be practically useful; while a lecture delivered extemporaneously upon such of the cases, whether common or otherwise, as may present themselves during the physician's or surgeon's visit,

requires but little preliminary labour on the part of the well-informed teacher, and is attended with a far more practically useful result to the hearer. A common ulcer, or a simple pleurisy, may form an appropriate text on which the clinical professor may build a discourse pregnant with instruction to his pupils; and if it be said that such cases are of common and every-day occurrence, we reply, that that is the very reason why they should be frequently dwelt upon. The subject of clinical teaching is too extensive to allow us to enter into it at large upon the present occasion, but we shall return to it at a future opportunity.

Treatment of Union Surgeons by Poor-Law Guardians. An inquest was lately held at Heywood, on the body of Edmund Wild, aged 71, who died in the Bury workhouse. He had fractured the thigh-bone, and, after being admitted into the workhouse, died while under the care of Mr. Hinxman, one of the surgeons, from the effects of a bed-sore, the Board of Guardians having resolutely refused to supply either a water-bed or one of Hooper's cushions. At the inquest, the clerk to the Board said that the man died from injudicious treatment by the surgeon. The jury, however, in their verdict, censured the Guardians for want of proper attention to the deceased, in not forwarding such means as, in the opinion of the medical officers, were considered essential for obviating his disease, or endeavouring to make it less painful or fatal. An analogous case has also occurred at Southampton, in which the Guardians sought to fix blame on the medical attendant, on the ground that he had not detected a disease of the kidneys, which was discovered after death. The woman had been reported as suffering from disease of the liver; and had been refused out-door relief. The jury passed a vote of censure on the Guardians.

Honours conferred on Dr. De Carro, the disciple and friend of Dr. Edward Jenner. The Emperor of Austria has lately conferred the golden cross of the order of Civil Merit on the Chevalier Jean De Carro, M.D. (born at Geneva in 1770), the friend and apostle of Edward Jenner. After the ceremony, a banquet was given in honour of Dr. De Carro by M. Knoll, burgomaster of Carlsbad in Bohemia, where Dr. De Carro resides. During the evening, a collection was made for some poor families of the place. [Abridged from *Lancet*, Jan. 18th; and *Daily News*, Jan. 14th.]

The late Robert Liston, Esq. The Queen has lately granted a pension, of 100*l*. per annum, to the widow of the late Robert Liston, the eminent surgeon.

Testimonial to Dr. Paul of Elgin. Dr. Paul, of Elgin, a gentleman known to the profession by several original publications, and as an eminent practitioner for the last thirty years, has been lately requested to sit for his portrait, which, when finished, was presented to his family by a deputation composed of the magistrates and clergy of the town, as the spontaneous expression of gratitude for professional services, and respect for his long-tried character and conduct.

Adulterations of Articles of Food. The *Lancet* has commenced a series of valuable articles on the adulterations to which various substances, used as food, are subjected. The subjects which have been already noticed are coffee (January 4th) and sugar (January 18th and 25th). The microscopic and chemical characters, both of the pure substances, and of the adulterations and impurities are detailed, and illustrated by woodcuts; and the results of the examination of various specimens, procured from the shops, are given in detail. Great credit is due to the editors of the *Lancet* for the publication of the reports of their "Analytical Sanitary Commission". We heartily wish that their success, in promoting the dietetic welfare of the community, may be commensurate with the labour which they are bestowing on the subject.

Bequests to Hospitals. The late Thomas Ansaldo Hewson, Esq., has bequeathed the sum of 1000*l.* to University College Hospital, and 500*l.* to King's College Hospital. The late Mr. Bethune Morrison, of Naughten, Scotland, has left 500*l.* to the Dundee Royal Infirmary, and 200*l.* to the Dundee Lunatic Asylum. The executors of the late Colonel Cheape, of Girgenti, have paid 1500*l.* to each of five Infirmaries in Scotland.

Quintuple Birth. The *Deutsche Klinik* for November 23 states, that on the night of the 11th of that month, a peasant's wife, at Alt-Rehfeld, was safely delivered of five living male children. One lived three hours, another twelve; the other three survived. The mother was doing well.

APPOINTMENTS.

Bond, Dr. H. J. H., appointed Regius Professor of Medicine in the University of Cambridge, in the room of the late Dr. Haviland.
Childs, G. Borlase, Esq., elected Surgeon to the Metropolitan Free Hospital.
Pidduck, Dr. Isaac, elected Physician to the Bloomsbury Dispensary.
Ramskill, Dr. J. S., elected Physician to the Metropolitan Free Hospital.
Richardson, Dr. W., elected Physician to the Metropolitan Free Hospital.
Sandie, Dr. J. G., elected Physician to the Liverpool Dispensary.

OBITUARY.

Bailey, Dr., in Jamaica, of cholera, lately.
Brown, Dr. John, at Boston, aged 51, from suicide by prussic acid, on Jan. 9th.
Brownson, Dr. W. H., late Surgeon to Her Majesty's 2nd West India Regiment, at Brompton, aged 37, on 21st December.
Chambers, Dr. John, in Jamaica, of fever, lately.
Crichton, Dr. H. P., in Jamaica, of cholera, lately.
Duncan, John W., Esq., Assistant-Surgeon R.N.
Ewart, Dr. John, in Jamaica, of fever, lately.
Fishbourne, Dr. T. M., in Jamaica, of fever, lately.
Froom, T. N,, Esq., at Dunsford, near Exeter, aged 35, on 6th December.
Haviland, Dr. John, thirty-three years Regius Professor of Medicine in the University of Cambridge, aged 65, on 8th January.
Hickman, William, Esq., at Great Marlow, Bucks, aged 94, on 24th December.
Leuret, M., late Physician to the Bicêtre, Paris, at Nancy, lately.
Link, Professor, at Berlin, lately. He was celebrated as a botanist, and a writer on Natural Philosophy and Science.
Lucas, Dr., Assistant-Surgeon, 61st Foot, at Peshawur, in October last.
Macfadyen, Mr., in Jamica, of cholera, lately.
McDermott, Dr. C., in Jamaica, of cholera, lately.
Miles, Dr. John, at Bukee, aged 77, on 14th December.
Murcott, Dr., in Jamaica, of cholera, lately.
Palmer, Dr. A., in Jamaica, of cholera, lately.
Philip, John, Esq., Assistant-Physician R.N., at Edinburgh, on 13th December.
Scale, Dr. John D., at 7, Taunton Place, Regent's Park, of pneumonia, aged 36, on 21st December.
Scriven, Dr. G. A., at Deptford, from suicide by oxalic acid, aged 34, on Dec. 25th.
Squair, Dr. John, late Surgeon 8th Hussars, at Portobello, on 14th December.
Tabois, Dr., in Jamaica, of cholera, lately.
Tait, Dr., in Jamaica, of cholera, lately.
Wood, Dr. J. R., late of Glasgow, at 19, George Street, London, on 25th December

ORIGINAL COMMUNICATIONS.

ON THE PHYSICAL EXAMINATION OF THE ABDOMEN, IN HEALTH AND DISEASE.

By CHARLES J. B. WILLIAMS, M.D., F.R.S.

(Continued from page 97 of last Number.)

EXAMINATION OF THE ABDOMEN BY PALPATION.

[The following introduction to the subject of "Palpation" was inadvertently omitted at the commencement of the paper in the number for February.

Like the sight, the touch acquaints us with the form, size, and movements of objects; but it further instructs us with regard to their temperature, surface-feel, consistence, resistance, and weight; and in the case of soft, pliable, and yielding objects, such as the abdomen, the touch reaches beyond the surface, and may feel more or less of all the same properties in the deeper-seated parts. Thus by *palpation*, or *handling*, of the abdomen, we may learn far more than sight can teach us, of the physical properties, and therefore of the healthy or morbid condition, of its internal organs; and the more carefully we analyze these physical properties, and understand their relations to the parts which possess them, the more instructive will be the knowledge which we derive from them.

As to the sight, so also to the touch, the abdomen is made up of its walls and the viscera within them; and the latter being felt through the medium of the former, will be more or less distinct, according to the condition of the abdominal walls. When these are very thick or tense, it may be difficult to feel anything through them: when they are thin, and more especially when they are also flaccid, the condition of the contained parts may be determined with great nicety. The thickness of the walls depends chiefly on the quantity of fat, and where this is very great, palpation can only afford obscure results; the touch must be applied with considerable pressure, to reach beyond this superficial mass. The tension of the walls depends on the tonic contraction

of the abdominal muscles, often increased by voluntary restraint, under the apprehension of pain, or from nervousness; and it may greatly interfere with the examination by rendering the walls too hard to permit anything to be felt through them: but this muscular rigidity may generally be reduced by calming the patient's fears, and by diverting the attention from the region by questions on some other interesting topic regarding the health, whilst the hand is kept applied with a gentle pressure, and softly rubbed over the surface of the abdomen, until the muscles become relaxed, and the examination is properly effected.]

The palpable signs of *air in the peritoneum* are very characteristic. The usual moderately elastic softness of the abdomen is replaced by a tympanitic elasticity, remarkable for its resilient feel, and even on superficial pressure yielding the same light and springy resistance. Effused as air usually is suddenly in consequence of perforation of the alimentary canal, its phenomena may be much masked by the intense pain and other symptoms of severe disturbance which usually accompany that accident, and which, by spasmodic contraction of the abdominal muscles, render palpation difficult. In the absence of such symptoms, which are in themselves pretty significant, the physical diagnosis is easy, as in the following case.

A woman, 50 years of age, was admitted under my care for disease of the abdomen, which I considered malignant. The liver was much enlarged, with nodulated inequalities, and was an object of palpation at every visit. One day, before asking a question, or hearing the daily report, one touch of the epigastrium drew from me the exclamation—"Here's air in the peritoneum!" The region which before had presented the hard uneven resistance of the diseased liver, now felt soft, very elastic, and uniform on its very surface; like, in fact, a thin vulcanized India-rubber air-cushion moderately distended. The peculiarity of the feel, contrasted with the previous condition of the abdomen, made me sure that nothing but an extravasation of air could account for the change; and on further examination, the superficial tympanic sound, with metallic echo on percussion, and the gurgling near the surface at the sides, where liquid mixed with the air, confirmed the first impression. The patient had suffered more than usual pain, but was now easy, and her countenance calm, under an opiate; the pulse was, however, very rapid and thready, and the feet and legs becoming cold. She died in about twelve hours. The air was found in the peritoneum as indicated, occupying the whole front of the abdomen; the liver was large, and studded with cancerous tubera: lying underneath, and attached to it, was a cancerous mass involving the pylorus, duodenum, and transverse colon. The perforation was in the duodenum.

As peritoneal tympany, or pneumo-peritoneum, occurs only in case of perforation of the alimentary canal, its palpable signs as just described, and those of superficial tympanic stroke-sound with metallic tinkling, to be noticed hereafter, become evidences of the occurrence of that mortal accident. But perforation may occur without the extravasation of sufficient air to produce the signs; their absence, therefore, will not disprove the existence of perforation. In the formation

of limited fistulæ in the peritoneum and walls of the abdomen communicating with the intestines, the superficial gurgling or croaking under the pressure of the fingers is a very palpable sign; I have met with it in more than one case. It is more distinct and superficial than the gurgling of reducible herniæ.

PALPABLE SIGNS OF SOLID INDURATIONS AND ENLARGEMENTS IN THE ABDOMEN.

Solid bodies of flattened shape are sometimes met with in the walls of the abdomen, underneath the integuments, or between the abdominal muscles and peritoneum. In the former situation, they can be felt to move freely on the muscles, even when these are tightened. When attached to the abdominal peritoneum, they may be felt to remain fixed during the movements of respiration, which would carry them a little upwards and downwards, were they connected with the abdominal viscera. In making observations on these movements, the umbilicus, linea alba, or some other conspicuous object on the walls, will assist the eye or the hand in seeing and feeling what is attached to the walls, and what moves with the viscera underneath. Indurated patches in the situations now alluded to, I have known both of a cacoplastic or low exudatory, and of a malignant kind; the latter being commonly distinguished by its penetrating through several textures, and often presenting nodular irregularities.

Laminar indurations of the omentum, or intestinal peritoneum, may be felt by careful palpation when the walls are relaxed, practised both perpendicularly, and from side to side. Gentle perpendicular pressure detects the greater resistance offered by the induration, as compared with adjoining spots; but delicate lateral palpation may even detect the edges of the induration, and determine its thickness, as well as its superficial character. The absence of resistance on firm pressure, and of dulness on percussion, distinguishes these superficial indurations from more solid tumours.

A thickened state of the coats of the intestines is of much commoner occurrence than is generally supposed; and in most instances of chronic diarrhœa it can be detected by careful palpation in the region of the cæcum, or of the ascending or the sigmoid colon. For this examination the patient should be in bed, lying flat on the back, with the muscles quite relaxed; the abdomen is then to be felt by gentle steady pressure with the flat fingers, gradually slided to successive parts; the greater superficial resistance, in one or more of the regions just mentioned, will then become very obvious; and it is sometimes, but not always, accompanied by tenderness on deeper pressure in the same spot. Although feeling thus hard to superficial pressure, it yields with some resistance to firmer pressure, and gives a tympanitic sound on percussion. This thickening of the large intestine apparently results from a low inflammation of a chronic or subacute kind, and is usually attended by occasional attacks of diarrhœa, or even slight dysentery, sometimes alternated with constipation. A married lady, æt. 30, had for more than twelve months been liable to attacks of severe diarrhœa, which greatly reduced the flesh and strength; the catamenia became irregular and defective; and the whole constitutional powers were failing. Travelling on the continent had been

tried with temporary benefit; but the attacks continued to recur; and the bowels being confined in the intervals, and the appetite bad, no progress was made towards recovery. In this case I found distinct fulness, with superficial resistance, from the right iliac to the hypochondriac region; and an irregular but moveable resistance was also felt in the left iliac fossa. All this tract was tender on pressure, even when diarrhœa was absent. Counter-irritation over the course of the colon, first by a blister, and subsequently by solution of iodine, using, at the same time, an India-rubber belt, lined with soft wool, succeeded in removing the thickening of the bowel. After a month's treatment, there was no return of diarrhœa, and the health has been uniformly good ever since, a period of five years. In another case, that of a married lady, æt. about 36, severe abdominal irritation, with dysenteric diarrhœa, was brought on by too frequently bathing in the sea. The symptoms were repeatedly relieved by astringents, farinaceous diet, and confinement to bed; but they always recurred so soon as she attempted to get up and return to the usual diet. Being summoned to Ramsgate to see her, I found, on examination of the abdomen, a very palpable hardness and fulness along the whole tract of the colon, from the cæcum to the sigmoid flexure inclusive; and it was only after repeated blistering, and counter-irritation with iodine over these parts, whilst the bowels were regulated by small doses of sulphate of copper and narcotic extracts, with occasional mild alterative aperients, that a permanent cure was effected. In many cases of chronic diarrhœa and dysentery I have detected the same physical signs of thickening of the large intestine, and have by them been guided to the same successful mode of treatment.

In these cases the thickening of the intestine is probably the result of a low inflammation, sometimes excited by the injudicious administration of astringents to stop a diarrhœa. The thickened bowel has an irritable mucous membrane, whilst the regular and efficient contraction of its muscular coat is impeded by the deposit, which consists partly of thickened epithelium, and partly of exudatory matter under the mucous membrane. Hence, too, the combination, or alternation of irritative diarrhœa with costiveness and retention of scybala. Practitioners are apt to regard the scybala as the true cause of the irritation and diarrhœa; and doubtless they may contribute to keep it up: but their repeated formation and retention are really due to the altered structure and impeded function of the intestine, and are to be prevented only when its motory and secreting powers are properly restored.

In feeling for these intestinal thickenings, some variation of manipulation is necessary in different parts of the abdomen. The cæcum is usually quite superficial, often forming a fulness or prominence in the right iliac region, and extending more or less towards the linea alba and upwards. Its thickening is detected by gentle pressure meeting with more resistance and hardness than is felt in the hypogastric or left iliac regions, whilst the sound on percussion is still hollow, although often less so than usual. The ascending and transverse parts of the colon usually lie deeper; and, if within reach, require more pressure to test their resistance; which, if increased, is to be distinguished from that of an enlarged liver by being more rounded, and with a hollow stroke-sound. The sigmoid flexure of the colon

lies still deeper in the left iliac fossa; and, if thickened, is to be felt from the left side, by the flat fingers gradually pressed with a rotating motion and increasing firmness; it is usually contracted, contains little or no air, and feels like a large curved cord, in some degree moveable, in the hollow of the ilium.

The thickening of the intestine, hitherto described, is supposed to be of inflammatory origin; but it may save repetition to mention here, that *malignant disease* may grow in the same situations, present somewhat of the same signs, and be detected by similar manipulation. The diagnosis of malignant formations may generally be established, both by reference to the constitutional symptoms, and by peculiarities in the local disease. On the former we need not dwell at present. The peculiarities of malignant growths, as distinguished from inflammatory deposits, consist in their assuming more the form of circumscribed tumours; both from their being developed in more nodular masses, and from their disposition to penetrate and amass together contiguous tissues and organs, and further to involve them in their ulterior processes of irritation, contraction, ulceration, etc. Even diffused malignant growths on the intestines may therefore generally be distinguished from simple inflammatory thickening by their greater irregularity of surface, being more nodulated and circumscribed, and often connected with a deeper-seated tumour, which affords much more than the superficial resistance of thickened intestines.[1]

Malignant disease of the stomach, when affecting the pyloric end, and often involving a portion of the duodenum, colon, and pancreas, in most cases forms a palpable tumour, to be felt on pressing more or less deeply to the right of the epigastrium. Much tact and tenderness are often required to enable the hand to reach deep enough to feel the tumour; and a favourable opportunity should be taken when the bowels are empty, and when there is the least amount of sickness or tendency to pain. The pressure should be rotatory and gradual, in the direction of the spine. The tumour, when felt, is rarely quite dull on percussion, and often pulsates, from the motion of the subjacent aorta; but the pulse is in one direction only, and not diastolic, or enlarging at each beat, as in the case of aneurism. The tumour is easily distinguished from the liver by its being deeper seated; or if it be larger and approach the surface, by the tympanitic interval between it and the mass of the liver, the signs of which belong to the

[1] The following case is uncommon, but I mention it as both exceptional, and yet illustrative of the importance of physical examination. An unmarried lady, aged 26, who had always been delicate, came under my care for gastritic dyspepsia, which resisted all the usual measures. Intolerance of all nutritious food, and consequent wasting, ensued, and subsequently obstinate constipation and great distention of the intestines. An eminent physician who was called into consultation, considered the case hysterical, and advised the persevering use of galbanum and colocynth purges, aided by the rue enema. I did not concur in that opinion; because by careful palpation I had distinctly felt a thickening of a portion of the intestines. I supposed this thickening to be the result of chronic inflammation, and apprehended ulceration and perforation should the obstruction continue. Perforation and speedy death did ensue; and examination discovered very extensive thickening of both stomach and ileum; but the thickening was from malignant disease, which in so young a person I did not anticipate. The ileocæcal valve was almost closed by stricture, and the intestine above was ulcerated and perforated.

lower right ribs, and upper part of the epigastrium. Scirrhus of the cardiac end of the stomach is less within the reach of palpation, as this portion lies both deeper and more under the ribs. I cannot now call to my recollection a case in which I have been able to feel the tumour where it was confined to this end of the stomach. On the other hand, I can scarcely remember one case of malignant disease in other parts of the stomach and intestines, where, sooner or later, a tumour or induration has not been felt, so as to serve to confirm a diagnosis, which is often too evident from the general symptoms.

When malignant disease causes obstruction of the intestines, those portions above the impediment may become enormously distended, and their outline may often be traced by palpation, as in cases of fæculent accumulation; but this tends to put out of reach the obstructing lesion, which is buried in the accumulated mass. If the stricture be in the rectum or sigmoid flexure, its presence may sometimes be inferred by the obstacle opposed to a finger, to a bougie, or to the contents of an enema introduced by the rectum.

Solid massive tumours in the abdomen, as those of a much enlarged liver or spleen, present certain palpable characters in common, which should be noticed before we advert to the individual varieties. In proportion to the mass which is in contact with the walls of the abdomen, an enlarged liver or spleen will present the resistance and weight of a solid body, soft or hard, as the case may be. When soft, it may not feel much more resisting and inelastic than the abdomen in general, especially if felt only in points with the ends of the fingers; but if pressed more in mass with the flat of the fingers, and more particularly if the weight of the tumour be brought to bear against them by a leaning forward or prone posture, the feel of the solid enlargement, although soft, becomes quite palpable, and may be contrasted with that of other parts of the abdomen containing intestines only. Again, a slight abrupt impulse given to one point of a soft solid may cause a kind of undulatory movement through it, which might be mistaken for fluctuation; but besides its wanting the soft and gravitating character of liquid motion, a distinction may be made by giving the body a flat push on one side, which will be communicated to the hand on the opposite side with the impulse peculiar to a solid body. In fact, by a little management, we may generally contrive so to handle and feel the tumour, as to infer from its consistence, resistance, weight, and shape, the nature of its material.

The test is easier when the tumour is harder and more dense, because then its greater resistance and weight are more obvious, and so strikingly contrast with those of the abdomen in general, that it is easy to feel the outline of the mass, and trace its precise shape and position. Its continuity, likewise, from front to back, or from side to side, can be determined by finding that a push or impulse is transferred by it, which it would not be, if fluid or air intervened.

In many such cases the weight of this tumour causes some variation in its position with change of posture; and we may avail ourselves of this to ascertain its form and dimensions, and its relation to the other contents of the abdomen. This is especially needful in the common combination of solid tumours with liquid effusion; the liquid, if

abundant, putting the tumour out of reach, until, by its greater weight, it is brought to bear down against the walls.

The *liver* may enlarge in any or in every direction, upwards, downwards, and outwards, in front, at the side, and behind. Except when upwards only, a very rare case, the enlargement may be detected by palpation, as well as by percussion and inspection. The outward bulge is more obvious to sight than to touch; but if at all considerable, it may readily be felt on passing the hand from above downwards, from the middle regions of the chest to the upper parts of the abdomen, making a comparison of the right with the left sides. The bulge of liver enlarged laterally then meets the hand in a way that can hardly escape notice, and if found to be dull on percussion, and resisting pressure, it may fairly be diagnosticated as such in cases where no opportunity is given for inspection. The most common mode of enlargement, however, is downwards, with more or less general fulness; and as this brings the organ below the margin of the ribs under the pliant walls of the abdomen, it becomes the especial object of examination by palpation. The amount and kind of enlargement will determine the degree of facility in detecting it. If the liver do not extend beyond an inch or so below the ribs, it may not be felt at all; for it must be remembered that its margin being thin, it may oppose to the fingers no palpable resistance, especially if the walls of the abdomen are at all thick. But if the organ reaches two or three inches below, even without any material thickening or increased density, the fingers can scarcely fail to feel its resistance, particularly when aided by comparing the pliancy of the abdomen in the left hypochondrium. When the liver is still more enlarged, its margin usually becomes thickened as well; and besides the very distinct resistance which its anterior surface offers to the fingers, the lower margin may now be felt as a distinct ridge by the fingers pressed into the abdomen below it, and then moved rather briskly upwards. For the examination of the liver, the sitting, standing, or leaning forward posture, answers best; the observer placing himself either in front, at the side, or behind, according as he can best apply his hands to the abdomen.

It is in the case of induration with enlargement, that disease of the liver is most obvious to palpation. There is then no need of comparison with other parts of the abdomen; the hard substance of the organ forming a tangible object, the surface, outline, and irregularities of which may be independently explored in all their details. In such cases we can often determine with great nicety whether the substance is granular or uniform; whether the edge retains its wedge-shape, or has become thick and rounded by deposit and the contractile process. We may often feel the under surface of the organ, and trace its inequalities, with the position and state of the gall-bladder.[1] Nor are these

[1] The following case is not less interesting in its diagnostic than in its pathological and therapeutic relations.

A dignitary of the Church, of sedentary habits, had for years been subject to attacks of severe pain in the hypochondria, attended with obstructed flow of bile, and generally followed by more or less jaundice. For some time these attacks were considered and treated as arising from gall-stones; but they had latterly become so frequent and severe, and the strength and flesh had been so much reduced, that great fears were entertained that there was malignant disease pre-

nice points of diagnosis matters of pathological or speculative interest only. They have a direct bearing on the prognosis of the case, and are by no means useless in guiding the treatment. The soft enlargements of the liver are in many instances tractable under remedial measures, especially those which increase and liquefy the secretion of the organ; and the transition to the state of induration is not so abrupt or universal as to preclude similar means from being highly useful, even where considerable hardening of the tissue has taken place; the salutary effect being generally attended by a palpable diminution of the hardness, as well as by a reduction of the dropsy, jaundice, and other consequences of the obstruction. In these more tractable cases of indurated liver, we do not feel the rugged surface and granular irregularities which are present in the more formidable kinds of cirrhosis; nor do we find the proofs of failure of function and degeneration of structures in the general symptoms—such as progressively failing appetite and strength; increasing jaundice and dropsy, although bile is excreted, and urine is not greatly deficient; gasping breathlessness, or orthopnœa; fluttering or rapid pulse; with the ominous arcus senilis, etc.—indications of the worst kind, which leave no hope of real recovery.

The alteration in the shape of the edge of the liver, from wedge-shaped to rounded, often occasions a displacement of the organ from its natural position, which it is important to notice in reference to its physical signs. So long as the liver retains its proper shape, its anterior surface remains in close contact with the abdominal walls, unless a liquid effusion happens to separate them, which is clearly evinced by the sign of *diahydric*[1] succussion before described. But when the lower margin becomes rounded, portions of intestines are apt to slip up between the walls and the liver, and to separate its lower

---

sent. On my first seeing him, he was much emaciated; the liver did not reach below the margin of the ribs, and there was no feeling of any tumour or hardness underneath. One spot, just below the right ribs, two inches from the ensiform cartilage, was pointed out as being always tender, and the seat of the most intense pain during the attacks; then, I was assured, it became the seat of a hard swelling. On one occasion only I felt this swelling; it was then soft and of a rounded shape, but the attack was on the decline. This seemed to me so much like a distended gall-bladder, and the whole case so like one of biliary concretion, that I caused a diligent search to be made in the evacuations. In a few days a gall-stone was found, consisting as usual of cholesterin. The diagnosis being thus clearly made out, and the usual means of treatment having failed, it occurred to me that the cod-liver oil, which I was then giving extensively to phthisical and cachectic patients, might prove a means of dissolving the concrete biliary matter, and of promoting a better secretion in the liver. It was given, and answered perfectly; only one slight attack happening after its use; appetite, flesh, and strength, were gradually restored, and the gentleman has been constantly engaged in his ecclesiastical duties for nearly three years. But what is worthy of remark is, that under this treatment the liver enlarged in size, so as to reach nearly two inches below the margin of the ribs, and the tender spot descended with it, and in the single slight attack which did occur, it formed a palpable fulness just two inches below its former position. In a few weeks the tenderness was removed. This gentleman consulted me for a slight ailment this day (Feb. 3). I found the liver still reaching between one and two inches below the margin of the ribs, but quite free from all tenderness or swelling.

[1] I propose this term (from *dia*, through, and *hudor*, water,) to express the characteristic sign of *striking through liquid*, noticed in this paper on the Palpable Signs of Liquid.

part more or less from them. The liver thus becomes partially enveloped in intestines, and can no longer be felt distinctly. The gurgling of the intervening bowel may often be felt on pressure; and the prone position may cause the weight of the liver to compress it for a time, but it is not easy to displace the intestine when the shape of the liver is thus altered; and it is necessary to be aware of the fact, or we may consider the liver to be much smaller than it really is.

It is not necessary to dwell on the varieties of extent and form of enlargement of the liver determinable by palpation; but there is one which is so peculiarly diagnosticated by it as to deserve mention. I allude to dimpled cancerous tubera in the liver. The shape of these tumours, rounded, flattened, and umbilicated, or with central depression, is so characteristic, and they so frequently rise from the anterior surface of the enlarged organ, that in as many as five or six cases I have been able to feel them through the walls during life, and announce their existence, and the consequently unfavourable prognosis. Two of these cases, modelled in wax, are preserved in the museum at University College.

The *spleen*, when only moderately enlarged, lies deeper than the liver, and with the stomach in front of it; therefore, in feeling for it, below the margin of the left ribs, we must use deeper palpation, aiming the fingers obliquely upwards and to the left, instead of the superficial direct perpendicular pressure practised in testing the right hypochondrium for the liver. Its peculiarity of shape also is equally apparent; for so soon as it is sufficiently enlarged to come within the reach of the fingers, it offers to them the resistance of a rounded and somewhat moveable body, meeting the fingers and slipping aside under their pressure. With a further amount of enlargement, the spleen reaches lower under the ribs and nearer to the surface; and it then becomes more easily palpable, both from its more accessible position, and from its bulk and weight opposing a more decided resistance to the fingers. In its greatest degrees of hypertrophy, the spleen extends more or less down the whole left side of the abdomen, approaching the umbilicus in front, and reaching nearly or quite to the left ilium. When thus greatly enlarged, it is in contact with the walls of the abdomen under the whole margin of the left ribs from the spine to the epigastrium, or near it; it occupies the whole lumbar, hypochondriac, and iliac regions of the left side, and may in parts extend even across the mesial line. To all these regions it gives the peculiar resistance of a heavy solid body; compact, and transmitting a flat, heavy impulse, or push, through its mass; but not often hard; usually smooth and even on all surfaces but that which forms its right boundary, on which rounded prominences and intervening indentations can be felt. These correspond with the internal margin or pelvis of the spleen, into which it receives its vessels. To the right lie the intestines, which, by their elastic feel and hollow sound, contrast well with the dead heavy mass occupying the left of the abdomen, and sometimes causing considerable enlargement of its whole bulk.

These physical characters are in most instances quite sufficient to identify an enlarged spleen; but they are further to be confirmed by the results of percussion, and by the general symptoms of pallid cachexia, which commonly accompany great enlargements of the

spleen. I must not omit to mention that the spleen, not being firmly sustained in its position like the liver or kidneys, may somewhat change its position according to the posture; and this, although it may prove an additional means of diagnosis, has sometimes been a source of error. In common with all the medical men who examined the case, I once mistook a much enlarged spleen for an ovarian tumour. It occupied the lower half of the abdomen; its upper margin reaching from the right iliac obliquely to the left lumbar region; and the rounded prominences of the upper surface were supposed to be cysts of an ovarian tumour. They proved to be the protuberances of the vascular or inner surface of the spleen, which had fallen completely out of its place, so that this surface now lay uppermost, whilst that which usually occupies the side rested on the pelvis.

The kidneys, from their deep position in the abdomen, might seem to be beyond the reach of palpation; but, except in cases of considerable thickness of the walls of the abdomen, or of their distension by the bulky contents of the intestines, or by effusion in the peritoneum, a little contrivance and tact will generally enable the hand to feel these glands sufficiently to detect any material enlargement, as well as to test their degree of sensibility. For this purpose it is necessary to displace the superjacent intestines; and this is to be accomplished by rotatory pressure, gradually, but steadily increased, until the hand sinks so deep in the abdomen as to feel its posterior walls. The kidneys occupy the most prominent part of these, on either side of the spine, beneath the lowest bend of the ribs in front, a little above the line of the umbilicus, and from two to four inches to the right or left of it. For making this examination, the patient should lie flat on the back, with the limbs straight, but the muscles all as much relaxed as possible. The observer should be on the side opposite to that of the kidney that he is going to examine; and he should change sides to feel for the other. The right hand is then to be applied below the ribs, the fingers pressed flatly with a rotatory movement towards the kidneys; the steadiness of the pressure being maintained, if necessary, by the left hand applied on the right. The right fingers then, in their rotatory pressure, glance over the interior lumbar region; and the lower half of each kidney may usually be felt as only a slight flattened convexity in their natural state; but, when enlarged, forming a palpable prominence of rounded form, and often painful on pressure, the pain being sometimes referred to the loin, and the course of the ureter, as well as to the site of the kidney itself. In effecting this examination, it is often necessary to take off the patient's attention by conversation, to prevent those muscular efforts in the chest and abdomen, which are excited by nervousness or dread of pain, and which greatly interfere with the success of the exploration. Hence very timid or sensitive persons can rarely be examined satisfactorily in this way. The left kidney is more easily reached than the right, on account of the greater resistance opposed to deep palpation on the right side by the liver. The right, however, lies a little lower in the abdomen; and this brings it, in part, from under the last ribs in the right lumbar region, which is a spot in which both the fulness and tenderness of an enlarged right kidney may often be detected.

The diagnosis of moderate enlargement, with tenderness of the

kidney, through deep palpation, is of great importance in relation to practical measures. Often, guided by it, have I succeeded in curing acute albuminuria, and in relieving that of a chronic character, by means of cupping, blisters to the loins, and hydragogue purgatives; and in many instances the reduction of the swelling of the kidney, with the entire disappearance of albumen and of granular cell-casts of the tubuli from the urine, and the restoration of the proper amount of excrementitious matter, has proved that the disease was merely congestive, or subinflammatory, and the cure has been permanent. In other instances the tenderness has subsided, but not the enlargement; and the urine, although improved, has given proofs of a remaining structural disease, in its never recovering a healthy standard in quantity, specific gravity, and freedom from albumen.

Very bulky enlargements of the kidneys are more readily detected by palpation, both in front and in the lumbar region; and their position, shape, and immobility, pretty well serve to distinguish them from other tumours. Cysts in the kidney, and the expansion of the gland by the purulent fluid of chronic pyelitis (formerly mistaken for abscess), may be felt as a rounded, soft, heavy, fluctuating tumour, in the lumbar and iliac regions. Malignant disease of the kidney is usually attended with considerable enlargement, which, from its irregular form, and from the amount of blood commonly present in the urine, in conjunction with the general history and other symptoms, will generally serve for the diagnosis.

In several instances, I have detected, by deep palpation, *enlargement and thickening of a ureter*, commonly in connexion with chronic pyelitis. It is felt as a hard cord-like body, deep in the iliac region, more or less moveable, and transmitting the pulsation of the iliac artery at the point at which it crosses it. The enlarged ureter is tender on pressure, and the pain shoots upwards to the loin, and downwards to the testicle of the same side.

Enlargement and induration of the mesenteric glands may be supposed to be a fit object for diagnosis by palpation, and by careful manipulation it may generally be detected; but not so readily as might be anticipated; for with it there often coexists so much tympanitic distension of the abdomen, as to prevent the hand from reaching the deeper parts. But by choosing times when the bowels have been well cleared, and by using firm flat palpation, with some rotatory movement, followed by an increased pressure towards the back, the nodular glandular tumours may often be discovered.

Further illustrations of the utility of palpation might be given in cases of solid ovarian and uterine tumours, of pregnancy, of psoas abscess, of malignant disease of the bladder, of pelvic abscess, etc., etc.; but this part of the subject has already exceeded my intended limits; and quite enough has been given to illustrate the principles of manual examination of the abdomen. In my next communication, the acoustic signs of the abdomen will be considered.

(To be continued.)

CASES OF LABOUR, COMPLICATED WITH ULCERATING CANCER OF THE WOMB: WITH REMARKS.

By HENRY OLDHAM, M.D., Obstetric Physician to, and Lecturer on Midwifery, etc., at Guy's Hospital.

Case I. Ulcerating Carcinoma of Cervix Uteri during Pregnancy—Breech Presentation—Rupture of Uterus. On the 17th of June 1847, Mrs. H., a poor woman, with a pale and anxious face, called at my house for advice. She was 33 years of age; had been married eight years, and was the mother of four children, whom she had carried well, and given birth to without difficulty or accident. She had suckled the last child for fourteen months; and, before weaning it, had again become pregnant, and was now seven months advanced in gestation.

The principal symptom of which she complained, was a frequent coloured discharge, which first came on a month after she was pregnant, and had continued, with but short intermissions, to the present time. It was now brought on by any exertion, or by straining to relieve the bowels. Four days since she had had an attack of bleeding, which came on like a menstrual period, the discharge being of a vivid red colour. It lasted in this way for two days, and was succeeded by a profuse watery discharge of a faint, but not very offensive smell. She was restless at night, feeble and low-spirited in doing the work of her family in the day, and she occasionally had a burning pain at the lower part of the abdomen and back; but the degree of pain which she suffered was far less than is usual with the same disease in the unimpregnated state. The child moved freely.

On making an examination, I found the cervix the seat of malignant disease, which had already destroyed a considerable portion of both lips of the os uteri, leaving a circular hole large enough to admit the tips of two fingers, with which the presenting part of the child could be felt through the membranes. The tissue of the cervix, around the os uteri, was thick, hard, and uneven; and a hardened, well-defined bar of solid matter could be felt on the anterior segment of the womb. The appreciable limit of the disease in this direction seemed to correspond to the os uteri internum. The finger could not reach sufficiently far posteriorly to ascertain the extent of tissue which had there become implicated; but, as far as could be felt, it was unusually hard and rigid. The examination caused some bleeding.

Mr. Wells, a gentleman in practice in the neighbourhood, from motives of humanity, and from interest in the case, undertook to attend her in her confinement. In consultation with him, it was agreed that she should be allowed to go on her full time, and that the manner of delivery should be determined by existing circumstances. She was to live as well as she was able, and to take some tonic medicine, and an opiate occasionally at night.

On the 31st July, I was requested to see Mrs. H——, who was reported to have been in labour for some hours: but, on visiting her, I found her to be suffering from an aggravated degree of false pains, mixed with much pain that was connected with her disease. On ex-

amination, I found that the disease had made progress in the cervix, which was lower in the pelvis, and more open. The extent of surface which was affected seemed considerable, including the whole interior of the canal of the cervix, which felt of a stony hardness, and broken up into a rough, deeply rutted, bleeding tissue. Having stretched my finger through this seemingly lengthened passage, I could feel the presenting part of the fœtus, which appeared to me to be the breech. An opiate was given, which produced some hours' rest, and much refreshed the patient.

On the night of the 3rd of August, Mr. Wells sent me word that Mrs. H. was in labour, and that the breech presented. On seeing her, I found that, under the influence of regular pains, the cervix had yielded somewhat, the os uteri being more open, and more dilatable; and the breech of the child was easily felt. The front wall of the cervix, however, was indurated, thick, and unyielding, like a mass of hardened mortar. The bladder was distended with urine, which was drawn off, to the amount of a pint and a half, with the catheter. She had vomited occasionally since labour had set in: her pulse was rapid and feeble; and her countenance had the sharp, pallid, anxious look so characteristic of an advanced cancer. The dilatation of the os uteri was not sufficiently advanced to allow of any interference, and I agreed to meet Mr. Wells again in a few hours; during which time he watched for any opportunity which might offer to help delivery.

At 7 A.M., on August 4th, I received a note from Mr. Wells, telling me that the poor woman had suddenly become collapsed, and was dying. Before I could reach her house, she had been dead about twenty minutes. Since I saw her, labour had gone on, with some effect on the dilatation of the os; but she had been vomiting, and had then become deathly faint, and moribund.

POST-MORTEM EXAMINATION. This was made on the same night, the weather being extremely hot. We found that already some marks of decomposition were visible on the body. On opening the abdomen, some bloody fluid, composed of liquor amnii and blood, ran out. The uterus was distended with gas; and on drawing it forward, the fœtus (a full-grown male) was found projecting half through a longitudinal rent, about five inches in length, in its back wall, beginning at the cervix and extending upwards on the body. The fœtus, uterus, and adjacent abdominal viscera, were all in a state of incipient putrefaction. The uterus and its appendages were removed, and taken to Guy's Hospital. The placenta, from the rapid progress of decomposition, separated from the uterus. The abdominal viscera were very cursorily examined, as the room was dimly lighted, and we were mainly intent on getting away the uterus; but, as far as we ascertained, they were free from disease.

The size of the uterus, and thickness of its walls, were natural. The whole inner surface of the cervix was thinned by malignant disease; and the structure was deeply furrowed and hard. The upper boundary of the disease, marking the inner opening of the cervix, was very clearly defined by an edge of healthy tissue belonging to the internal part of the body of the uterus, which was altogether free from malignant disease. The vagina also was healthy. On the posterior surface of the uterus, on the left side, was a small superficial

patch of malignant deposit; and, spreading from it to the ovary and tube of the same side, were numerous bands of false membranes. The right ovary, too, had been enveloped in a web of false membranes. There was a corpus luteum in the left ovary.

Case II. Carcinoma of Cervix Uteri—Pregnancy—Delivery by Craniotomy. In 1848, a poor woman, nearly 40 years of age, became an out-patient, under my care, at Guy's Hospital, for hard cancer of the cervix uteri, with occasional hæmorrhage, and a constant fœtid watery discharge. She had had syphilis some years before, and had lived a hard and destitute life. Her general health improved under the influence of tonic medicines, with some astringent and sedative wash to the uterus. I then lost sight of her.

About a year from this time, on May 7, 1849, Mr. Leadam, of Tooley Street, sent me word that this patient was in labour; and finding a great obstacle to delivery, and thinking that I should be interested in the case, he asked me to see her. I found that she had been in strong labour for some hours, and was getting weak and exhausted, but that the os uteri was prevented from dilatation by a mass of ulcerating cancer in the cervix, from whence a fœtid discharge was oozing away, which had inflamed and excoriated the external organs. At the time, I thought that the malignant disease had not gone on so rapidly during her pregnancy as I should have expected; but the extent of the cervix-tissue which had become infiltrated was considerable, and offered a formidable obstacle to delivery. The head was presenting, and could be felt through the disc of the os uteri, which, during labour, had become dilated to the size of a crown-piece.

To deliver her as soon as possible was imperative. I perforated the head, and freely emptied its contents; and, under the influence of uterine action, the bones collapsed well. I fixed the crotchet firmly on the inside of the presenting parietal bone, rather posteriorly; and being able to make powerful traction in this direction (which was the best for the head to pass in small compass) I had the satisfaction of finding it clear the hard narrow passage of the cervix with but little laceration of its structure. The remainder of the child was removed without difficulty. The placenta was strongly adherent, and was obliged to be peeled off with the hand.

I have since been informed by Mr. Leadam, that the woman lived about a month. On inspection after death, the cervix was found to be the seat of malignant ulceration; and on the posterior wall of the vagina, close to the cervix, were some ulcerated patches which had perforated the walls of the vagina, and communicated with the pelvic peritoneum. Peritonitis, of a low form, had supervened, and there was some purulent effusion in the peritoneum. There was a small cyst, of the size of a chestnut, in the right ovary.

Case III. Cancer of the Uterus and Vagina—Death of Fœtus in Utero—Easy Birth—Perforation of Vagina. I saw Mrs. P——, a poor woman, 42 years of age, on the 26th July 1850. She had been married twenty-three years, and had had twelve children. She had been confined six weeks. When one month gone in her last pregnancy, she began to have watery discharges with bleeding, and suffered severe pain in the loins, hips, and legs, so that

sometimes she could neither sit down nor move about. Sexual coitus brought on bleeding, and was forbidden. She suffered much from constipation. When these symptoms first appeared, she sought advice from an experienced medical man, who told her that she had cancer of the womb; but, at different times during her pregnancy, assured her she was not pregnant, although her own confidence in the fact of her pregnancy remained unshaken. She was suddenly seized with labour pains on June 9th, 1850, after she had gone her full time, according to her reckoning, and was easily delivered of a dead male child. The placenta was expelled without difficulty; but both the child and the secundines were putrid. Since this time, she had been getting worse; the discharges of blood and fœtid watery discharge had been mixed with fæculent matter. She was cachectic, and greatly exhausted, and a constant sufferer from cancer pains.

On examination, the cervix uteri, and the posterior wall of the vagina, were found extensively destroyed by ulcerating carcinoma; and there was an opening into the rectum, through which the fæces passed. The disease was in an advanced stage; and her feeble constitutional power seemed unlikely to hold out long against the exhaustion produced by it.

Remarks. The preceding cases are instances of an extremely rare complication of pregnancy and labour, and one which, when viewed in relation to delivery, is of practical importance. They were all three cases of carcinoma of the cervix in a state of ulceration, and not of the fungoid or softer form of malignant disease. Neither are they to be associated with what has been termed the scirrhous os uteri in an early stage, by which is meant, either entirely or partially, a hard, somewhat large, and nodulated cervix, but without ulceration. This morbid condition, so common in the unimpregnated state as the result of chronic inflammation, may also exist in pregnancy, although it usually becomes softened as gestation advances, by the accumulation of the mucous secretion of the glands of the cervix, and the large supply of blood, and offers but little impediment to labour. Cases of this kind have been classed as cases of cancer with pregnancy, but without any conclusive proof of their being really cancerous. Here and there, as very rare exceptions, such cases may retain their induration and indisposition to dilate during labour. There is a preparation in the Museum at Guy's Hospital, where a large flap of the lower segment of the uterus was separated after a long first stage of labour; but there is nothing in the swollen and indurated cervix to indicate malignant deposit. I doubt very much whether any one, who has so thoroughly investigated the subject as to know when he has failed as well as when he has been right, would have any confidence, from a physical examination of the cervix, in pronouncing a disease to be carcinoma before it had begun to break down. Directly this process begins, it may be detected by a kind of brittleness of the edge of the os, or inner surface of the cervix, on a hard base, which is very characteristic of the commencing work of destruction. But there is nothing in the touch of the antecedent "scirrhus" to distinguish a benign and curable from a cancerous and incurable induration.

In Case III, the posterior wall of the vagina was implicated in the

disease; but in the other two it was confined to the cervix, converting this part of the uterus, towards the end of pregnancy, into a rugged indurated channel, involving a large amount of structure, and offering a solid unyielding obstacle to the progress of uterine dilatation.

The possibility of impregnation occurring in cases of incipient, or even open cancer of the cervix, notwithstanding the bleeding and watery discharge, is authenticated by several recorded cases,[1] and confirmed by the present instances. And however improbable such a concurrence may be, yet it is an important point in practice to give due weight to any signs or suspicion of pregnancy, to note them, and to carefully investigate them, with the view of deciding this question. In the third case, in spite of the woman's own assurance of being pregnant, this precaution was omitted. In the number of cases of cancer of the neck of the womb which come before me, especially in hospital practice, I have been struck with the comparative frequency of sexual intercouse between husband and wife, when it would be thought that the fœtid discharge and bleeding would have secured its voluntary suspension. The effect of the discharges on the glans penis in these cases, with but rare exceptions, is not irritating; and the possibility of pregnancy, during the child-bearing age, independently of the injury to the woman when the cancer is ulcerating, ought to warn the practitioner to take care that sexual connexion be forbidden.

When pregnancy is known to be present, and the fact of a pre-existing cancer has not been ascertained, it is possible that the signs of the development of the disease may be confounded with some of the morbid states of pregnancy; and palliative measures may be alone prescribed. In the first case, no vaginal examination had been made before the woman applied to me at the seventh month, although she had been previously under medical care, and no suspicion of so serious a disease had been entertained. It is always desirable to examine the uterus *per vaginam*, and to ascertain the condition of the cervix, if bleeding comes on frequently during pregnancy, although it may not amount to a profuse flow at any time; especially if it be brought on after walking, or straining, or during the sexual act, and if it be followed by a watery, or thin purulent discharge, with a more or less fœtid odour. Symptoms like these would warrant a strong suspicion of malignant disease; but, until the parts are examined, no certainty can be arrived at. It has happened to me to entertain this suspicion, when the case has turned out to be one of a few warts within the labia, whose fœtid secretion has, from neglect of cleanliness, collected about the parts; and the occasional small bleedings have come from a neglected ulceration of the cervix, whose vascularity has increased with pregnancy. A more common case is met with, especially in hospital practice, which, in its symptoms in connexion with early pregnancy, more closely resembles cancer. I mean induration of the cervix, with a granular suppurating surface within its channel, the result of chronic syphilis. This may, or may not be associated with thickening of the cellular tissue of the labia and œdematous effusion, with fissures and excoriations about the external organs. When pregnancy occurs under these circumstances, there is occasional bleed-

[1] See Dr. Robert Lee's Clinical Midwifery. Second Edition, p. 90.

ing from the surface of the cervix, a thin, ichorous, acrimonious, and offensive discharge, and the aspect of the patient is akin to the malignant cachexy. I have felt the cervix in a case of this kind, and have doubted at first whether the disease were malignant. This is one of the cases in which the induration may sometimes last to the end of pregnancy, and oppose the dilatation of the os. The diagnosis of syphilis is to be formed from the previous history, and other existing indications of it in the integument, periosteum, etc. The progress of the disorders, during pregnancy, is different. The morbid conditions of the cervix, in the venereal state, do not become materially aggravated; but, on the contrary, the induration may become partially, or, I believe, even altogether effaced under the physiological softening of the cervix. Such a case is more like cancer at the beginning than at the end of gestation. True carcinoma of the cervix, although in some cases it appears to have been rather tardily developed, generally, as in the first case here recorded, rapidly progresses, destroying the inner surface of the cervix, and infiltrating and hardening the deeper and adjacent parts. When examined by the finger in an advanced state, there cannot well be any mistake about it. The circle of the os is more open than in normal pregnancy, from the positive loss of substance; while its edge, and the whole inner surface of the cervix, is rutted and indurated, with a surface which bleeds and breaks down under the touch of the finger; which, on being removed from the vagina, brings with it some of the fœtid discharge. If the finger be not introduced *within* the cervix, and the outer or vaginal surface of the cervix be not yet destroyed, this part of the lower segment of the uterus feels like a solid uneven tumour, which is interposed between the finger and the presenting part of the child. If there have been much bleeding, or a sudden hæmorrhage towards the end of pregnancy, and a clot have formed within the cervix, the malignant disease not having previously been known, the physical conditions may, when first felt, resemble placenta prævia; especially if the disease be of a fungoid character. If the finger, however, be passed *within* the cervix, so as to displace or go beyond the clot, the solid uneven surface of the cancerous mass will be perceptible.

The prognosis in cases of carcinomatous degeneration with pregnancy is most unfavourable to both mother and child. The mother may die from the exhausting effects of cancer,—viz., hæmorrhage, copious watery discharge, vomiting, etc., before labour sets in. She may die undelivered, from ruptured uterus, or of exhaustion from protracted labour. Or, if she survive the immediate perils of delivery, she may sink exhausted a few hours or a day or two afterwards. If this does not happen, the disease generally goes on more rapidly, perhaps rendered less tolerable from some injury to the soft parts by the delivery, and ends in a few weeks, or possibly a few months, in death.

The death of the child is very common. It frequently happens (in about a third of the cases) that premature labour, between the sixth and seventh month, spontaneously ensues, the child sometimes having lain dead and putrid in the uterus, and then easily escaping during labour, as in Case III; this is certainly the most favourable termination for the mother. In other cases it is necessary to destroy it to effect delivery; or it may die in the course of delivery, as in Case I.

I know of no facts to shew whether the few who are born alive, and live, inherit the taint of cancer; but assuredly such a child would need the breast-milk of a healthy wet-nurse, and the same hygienic care and solicitude in its rearing which are given to scrofulous children.

Treatment. Some cases are recorded in which parturition at term has been accomplished by the natural powers, the mother surviving the act,[1] and the child being born alive. But so favourable a termination of labour, however it may be hoped for, is hardly to be expected. Death of the fœtus at the sixth or seventh month, its retention and putrefaction in the uterus, and its comparatively easy birth, have already been alluded to, and may be reckoned upon as probable events.

Our principal resources in the management of such cases are the artificial induction of premature labour, lessening the child's head, dividing the diseased structures, and the Cæsarean section.

Dr. Robert Lee's opinion, with reference to the first of these operations, is very decided. "If abortion", says he,[2] "does not take place where pregnancy exists with cancer of the os uteri in an advanced stage, the membranes of the ovum should be perforated if possible, and at the seventh and half month if the disease is less extensive." When I saw the subject of the first case which has been related, at the seventh month of her pregnancy, I considered the propriety of puncturing the membranes; but I determined against it. There would not have been the difficulty and even danger in doing so, which in some cases must be encountered in order to perform it, and which, I apprehend, might be sufficient to deter the practitioner from undertaking it. If the cervix were blocked up by cancerous disease, which must be passed through or broken down in order to reach the membranes, causing thereby serious hæmorrhage, then this operation ought to be avoided. But the membranes in my case could be touched, and might have been easily perforated. It appeared to me, however, that pregnancy, instead of aggravating the suffering of the patient, had rather lessened it, and I thought it something to gain two more months of life and comparative relief in a disease which could not but end fatally in a short time. The extent of disease at this time would, in my judgment, have been a most serious obstacle to the passage of a seven months' child, which would have probably needed instrumental assistance for its delivery, and the exposure of the diseased structures to the chance of laceration, and of the mother to the utmost peril. I could see nothing in the delivery of a seven months' child, which could so exempt the woman from danger as to counterbalance the positive benefit of a prospective life of two months to her. I therefore preferred to meet whatever increased difficulty might arise from a large child when labour came on, to bringing on by my own act, a crisis which was full of peril. I doubt the prudence of inducing premature labour in these cases as a rule. On the contrary, the rule with me would be, to leave the whole care of pregnancy and the time of labour to nature, and to do all that I could to alleviate suffering and urgent symptoms, and to preserve to the parent as much as possible of the nine months of gestation, which forms no inconsiderable part of the duration of a case of cancer.

When labour sets in, we must be guided in our choice of the method

[1] Lever (Dr. J. C. W.) Case in Guy's Hospital Reports, April 1842.
[2] Lee (Dr. Robert). Clinical Midwifery. Second Edition, p. 94.

of delivery by circumstances. It is desirable not to interfere, as long as the patient's powers and the strength of uterine action are well sustained in the efforts to dilate the os. It may happen, that suddenly the diseased mass will give way, and the lower portion of the uterus be either rent or detached, and carried before the head in its sudden escape into the vagina. But if the vital powers, already enfeebled by the drain from the diseased part, begin to fail, and the os uteri be still insuperably rigid and undilated, it has been recommended to make incisions through the obstructing portion, with the hope of giving room for the passage of the fœtus. In the two cases above related, this procedure appeared to be quite impracticable. The whole circle of the cervix was so implicated in the disease, and the indurated matter was so deep and massive, that there was no edge to cut, and an incision would have merely inflicted a wound upon the diseased structures and have caused them to bleed, without opening a way for the escape of the child. Any surgical operation of this kind, to be effectual at all, would require the cutting out of a mass of the cancer, which would be hazardous in the extreme, and indeed impracticable. Incisions through the cervix are only available for the purposes of delivery in those extremely rare cases when the cervix-tissue is hard and unyielding, but not from cancer (unless in a very early stage), and does not open under the forces of labour, which may have been spent upon it until the cervix is inflamed, and the female well nigh exhausted. The os may then be dilated by the knife, and the operation is well-defined, easy of accomplishment, and, as far as it has been performed, effectual in its purpose.

Abandoning therefore the idea of incision in these cases, there is the alternative between craniotomy and the Cæsarean section. The second case terminated as favourably by the first operation as could have been expected, but still it ended with the birth of a mutilated child, and the death of the mother one month afterwards. Had the disease made a little more progress, had it been as great as in the first case, the woman, in all probability, would have died undelivered, so difficult would it have been to remove the child by the crotchet, with the feeble endurance of the patient. I cannot but think, that the immediate risk of death to the mother, when the disease is much advanced, setting aside all consideration of the child, is as great in delivering by craniotomy as the Cæsarean section; and on the score of suffering, the latter is certainly the most favourable. When, however, after a careful study of the case, there is a prospect of delivering through the natural passages (as in Case II), although it be discouraging, and, at the best, must be attended with great risk, yet it is desirable to give the preference to it. But if the patient's powers seem quite unequal to sustain the shock and suffering of a protracted delivery through structures which will bleed and lacerate, and if the *fœtal heart is heard to beat*, I think that the Cæsarean section offers a speedy and a certain delivery, with no greater hazard, imminent though it be, and at the same time may rescue the child. The preservation of a child's life, under circumstances of hopeless disease of the mother, ought to turn the balance in the consideration of the means employed in its favour. In such cases, auscultation of the abdomen, to hear the fœtal heart, on which alone we can safely rely for the fœtus being alive,

ought to be attended to. This ought to be ascertained in any case so complicated, during that part of labour which is entrusted to the natural powers, because the sudden death of the mother from rupture of the uterus, as in Case 1, or from sudden and rapid exhaustion, may require the abdomen and uterus to be opened to save the child. A want of preparation, and an uncertainty as to the life of the child, may just let the moment slip by in which the child might be preserved.

The moderate inhalation of chloroform, in cases of this kind, would be most desirable; but the friends of the patient ought to be clearly apprised of the chance of sudden death from the disease itself, so that, should it happen, it may not be ascribed to the chloroform.

13, Devonshire Square, Bishopsgate Street, February 1851.

CASE OF LABOUR COMPLICATED WITH CAULIFLOWER EXCRESCENCE OF THE UTERUS: WITH REMARKS ON THAT DISEASE.

By JOHN ROSE CORMACK, M.D., F.R.S.E., etc.

(Read before the Medical Society of London, Nov. 30, 1850.)

THE case which I am about to bring under the notice of the Society is instructive, when viewed in connexion with other recorded cases of the same disease. It calls attention to the use of certain *palliative medicines;* and it likewise brings under our notice *excision* as a means of cure, or of prolonging life when the malady cannot be extirpated. It is also a remarkable case, from the circumstance of both the patient and her husband having been ignorant of the existence of disease, till I discovered it when called in at the end of the natural term of gestation.

During September 1847, I was requested by Mrs. G., aged 30, married for five years, and the mother of one child, to attend her in her approaching confinement, which she said she expected about the end of November. She had had two miscarriages. She said that her general health was good, and that since the third month of her pregnancy she had enjoyed better health than since the birth of her child. Some months before she became in the family way, she had suffered greatly from menorrhagia; and being then in Edinburgh, she went to consult Dr. Simpson. He was not at home, but she saw his assistant, who prescribed, and requested her to return on a future day to see the Professor. Finding great benefit from the medicine ordered (which, I believe, was gallic acid), she did not go back; and had never since asked, nor, as she supposed, required medical advice. She said, that about once a month she had had, during her pregnancy, a slight coloured discharge for a day or two, and also some colourless discharge; but that as this had been the case during her first pregnancy, and as it did not seem to weaken her, she was not uneasy about it.

From the day in September when she asked me to attend her in her confinement, till I was actually called to her in labour on the 28th of November, she never made the slightest complaint to me,

though I saw her frequently. During that period, she took much exercise; and she did so, not only with impunity, but with advantage to her general health.

About 5 P.M. on the 28th of November, I was summoned to attend immediately upon Mrs. G., who, I was informed, was then in labour. Upon my arrival, in half an hour afterwards, at her bedside, I found that she was not in pain; and, according to her own statement, and that of the nurse, she had hardly experienced any symptoms which resembled approaching parturition, except that she had discharged, *per vaginam*, a watery fluid in such abundance as to soak through the bed. I was told that the membranes had been ruptured, and that the waters were still coming in large gushes. As I entered, the discharge was observed for the first time to have given a sanguineous stain to the linen: and on proceeding to make an examination, I found her bathed in blood. She suddenly became very faint; and from the blanching of the countenance and the ebbing pulse, it was evident that the discharge from the vagina was telling rapidly and dangerously upon the vital powers. Upon introducing the finger, I felt—surrounded by soft and imperfect clots—an irregular, tolerably firm, and somewhat elastic mass, obstructing the upper part of the vagina. From the sensation which this mass communicated, and from the alarming way in which blood was flowing, I at first suspected that I had to deal with a case of placenta prævia. A moment, however, sufficed to remove this erroneous impression; for I found that I was easily able to carry my finger round the base of the tumour, and to make out that it did not proceed from the interior of the uterus, but was attached around its orifice, externally, and chiefly to the anterior lip. At this time, the os uteri was just sufficiently patulous to admit the point of the fore finger.

My first proceeding was to inject a strong solution of alum into the vagina; taking care that it reached and thoroughly bathed the os and cervix uteri. I next introduced a compress saturated with the same lotion, and then firmly plugged the vagina. I also had an opiate enema administered by the rectum. She soon fell asleep, and in two hours awoke refreshed, though very weak. During this time, I learned from the husband that the colourless discharge which she had before spoken of to me was watery and limpid, and not like mucus. This was afterwards confirmed by herself; and before leaving the house, I announced to both parties the nature of the case:—that there was a growth from the uterus, from which the water and blood had poured; that the membranes were still unruptured; and that labour had hardly commenced.

At six in the morning of the 29th, I was sent for in consequence of the pains having become sharp and regular. There had been no more loss of blood, and the pulse and general condition of the patient had so much improved, that I resolved to withdraw the plug (which was causing much discomfort), and satisfy myself as to the state of matters by making a digital examination.

The plug was found to be saturated with a reddened fluid, and to yield a repulsive odour, much resembling that of very fœtid lochial discharge. The tumour which had before been large and

turgid, could now be best compared to a superficial roughness, amid which were some more decided elevations. The os and cervix were rather tender to the touch, and so they had been at the first examination, though no sensation was communicated to the patient by freely manipulating the tumour. For the next eleven hours nothing remarkable occurred. There was a great drain from the seat of the disease of a fluid, which may be well compared to dirty and faintly reddened water. This, when excessive, was generally arrested or moderated, by injecting alum and using the plug. At 5 P.M., the labour pains became strong and frequent, but the os uteri did not dilate in proportion, and at this time it felt rigid, and on one side angular. I now introduced within the os a piece of dry sponge smeared with oil. From this time the pains became almost constant, and the dilatation of the os was evidently considerable at 7 o'clock. For some hours there had been little loss of blood; and till 8 P.M. I did not think that any further interference was likely to be required. At this time, however, there was a sudden accession of hæmorrhage; and as the os uteri was now pretty well dilated, I punctured the membranes, and administered three successive doses of the ergot of rye. A living child was born at 9 o'clock; the placenta soon followed; and the uterus contracted naturally. After taking some tea with toast and a little brandy, she fell asleep; and I then left her with pretty a good pulse.

On the following morning, I found that she had passed an excellent night, without requiring to take the opiate draught which I had conditionally ordered. I found the tumour had regained very much of the same character as when I first explored it, though it was much less bulky. It was still destitute of sensation, but around its base there was a good deal of tenderness complained of. Everything went on well till the fourteenth day—the strength increasing, the ability to nurse good and improving. The lochial discharge — or at least a moderate sanguineous discharge—continued. In consequence of local pain, I was asked to examine the womb. I did so, and found a state of matters very similar to what I had found at my last examination. I took occasion, however, to explain the nature of the case, and to hint at the necessity which might arise for operative interference. She, however, could not be persuaded, that if she had so long had the disease without knowing it, it could now be necessary to regard it in so serious a light.

With difficulty she consented to a consultation. About the twentieth day after her confinement, Dr. Henry Bennet saw her along with me; and in consequence of the pain which she felt in the base of the tumour, and the return on two occasions of alarming hæmorrhage, we both agreed that it would be proper to remove the diseased mass, with the portion of the uterus to which it was attached, without much longer delay. She objected, however; and thus much precious time was lost, both as regarded relief from pain, and an ultimate cure.

Some time afterwards, when the disease had considerably advanced, when no sleep could be had at night without an opiate, and when there was a good deal of tenderness in the parts, she was seen by Professor Fergusson, who discountenanced operative interference, from his conviction that it would not accomplish a radical cure. He did not, however, absolutely negative the propriety of the proceeding,

should the sufferings of the patient so increase as to make her desire relief by the knife or ligature. The debility and timidity of the patient increased; and thus much more time was spent. I may here state, that during the first part of this time great abatement of the discharge was obtained by the internal administration of gallic acid; and that pain was restrained within the bounds of endurance by opiates. At last, it was only by an enormous consumption of morphia that life was made endurable; the attacks of hæmorrhage were frequent and frightful; and the whole of the cervix uteri and vagina was excoriated, from the foul discharge with which they were constantly bathed.

On the 6th of February 1848, at the urgent entreaty of the sufferer, Mr. Fergusson removed the diseased mass by the knife, having first put her under the full influence of chloroform, and dragged down the womb within reach. The excrescence was entirely removed, but the incision (though a large portion of the cervix was cut away), was necessarily through indurated structure. The portion of the uterus which was removed, presented hardly any indication of the spongy growth to which it had given a basement. Indeed, the naked eye could only detect a flabby granular surface; and the touch could only recognize hardness of tissue and roughness of surface. A gentleman who promised to make a microscopic examination of the excised parts unfortunately forgot to do so.

Severe sickness came on some hours after the operation, probably dependent upon the chloroform, which had been administered before and during the operation to cause anæsthesia. After this, she improved rapidly in her general health, notwithstanding several pretty severe attacks of hæmorrhage. The dreadful pain had now ceased to torment her; the appetite was good; and she was gaining flesh and strength. In a month after the operation she was able to walk out a little. About this time, however, she began to complain of shooting pains in the back and pelvic region, and occasionally at night was obliged to have recourse to an opiate to obtain sleep. The incised surface till this time had presented a smooth and healthy surface, both to the finger and to the eye; but now, upon examining with the speculum, it was found to have assumed a granular surface. This condition rapidly increased; and within two months from the operation, there was a fresh excrescence, sometimes as large as a pigeon's egg, and at other times not bigger than a hazel nut. From this growth a profuse watery discharge flowed at intervals; and as time advanced, she had every two or three days frightful hæmorrhage, which, on several occasions, had nearly proved fatal. The pain was constant and of the most agonizing character. Besides the free application of belladonna to the sacrum, she took for several weeks before her death so much as three ounces a day of the Edinburgh solution of the hydrochlorate of morphia, in clysters, and by the mouth. Ulceration went on rapidly; and the atmosphere of the room in which she lay was intolerably offensive from the discharge, though deodorizing agents were freely used.

At last this poor sufferer was released from life on the 17th July, the immediate cause of death being exhaustion, from which she never rallied, after one of the attacks of hæmorrhage already referred to. For the last three weeks of her existence these attacks had been so

sudden, so violent, and so frequent, that it had been found necessary to keep the vagina constantly firmly plugged. The parts were bathed with an infusion of opium, once every six hours, and a clean plug was changed at least once every twenty-four hours, but generally at shorter intervals.

Death occurred about seven months and a half after her delivery; and rather more than five months after the operation.

Examination of the Body forty-eight Hours after Death. This I made with the kind assistance of Dr. G. T. Gream and Mr. A. B. Barnes. The emaciation and anæmic condition of the body were excessive. The arch of the pubes was removed, and the abdomen laid open, so that the uterus and adjacent parts might in the first instance be examined without displacing or handling them. The cervix uteri was absent. The vaginal end of what remained of the uterus was ulcerated, as was likewise the whole of the upper part of the vagina. When carefully looked at, the surface of the uterus which had been incised was found to have on it the same flabby granulations or vascular excrescences, which were noticed in the portion removed by Mr. Fergusson. They were rather more florid. The surface on which these growths were implanted was of a hard and almost cartilaginous consistence. The body of the uterus was harder, and rather larger than natural. It was dark—as if stained with a pigment—on its peritoneal surface. The vagina at its upper part was deeply ulcerated, and was easily torn. The urethra, the bladder, the ovaries, and the rectum, were free from disease.

Remarks. It is *possible* that if the operation had been performed earlier in this case, the result might have been somewhat better. Even as it was, life was prolonged, and a brief respite from suffering was likewise obtained. The effect of the gallic acid in restraining the menorrhagia at an early stage of the disease is an interesting fact, confirming what every one in the habit of using this medicine must have observed,—that it rarely, if ever, fails to manifest its anti-hæmorrhagic virtues, even under circumstances apparently the most different It is a medicine which we may almost give *empirically* as a styptic, so wide is the range of its application: in menorrhagia, probably, no medicine is equal to it. Gallic acid, however, though useful in restraining the hæmorrhage depending upon cauliflower excrescence of the uterus, is not a remedy for that disease; which, so far as our knowledge at present extends, cannot, it may be safely stated, be cured by medicines or hygienic treatment.

Can cauliflower excrescence of the uterus be permanently eradicated by the knife or by the ligature? If not, can it be made less painful and less rapid in its course by surgical interference? These are the questions which demand answers.

Unfortunately, cauliflower excrescence of the uterus is not the seat of pain, except in its later stages; and therefore rarely comes under the notice of the medical adviser at that period when complete removal can only be hoped for. The case which I have detailed might have had a very different issue, if the diseased mass and the surface from which it sprang had been excised twelve months earlier,—at a time when the only symptom was the limpid discharge. Had the operation been tried with all convenient speed after delivery, the miserable existence which

the patient had after her confinement might have been ascribed by some to the use of the knife. The case must now, however, be held as proving with all others recorded, that such tumours, though they may long remain pretty stationary, at last inevitably terminate fatally. This fact is of itself a strong argument in favour of resorting to operative interference as early as possible, for it is then, if at all, that the morbid mass can be eradicated. In Mrs. G.'s case, when the operation was performed, a cure was not expected; and the knife was used only with the hope of accomplishing what was attained, a respite from impending death.

On the 3rd of Dec. 1845, Dr. Simpson read before the Medico-Chirurgical Society of Edinburgh a communication upon excision of the cervix uteri, in which he stated that out of eight cases in which he had performed this operation, in three the amputated vaginal portion of the cervix was the seat of what he terms "carcinomatous disease". In one of the cases, one of cauliflower excrescence, the patient had remained perfectly well from the date of the operation in 1840, and in the interval had given birth to and had nursed three healthy children. In a second patient, whose health and strength were greatly reduced, the excised part presented a tumour having all the microscopic and other characters of Müller's *carcinoma fasciculatum*. When Dr. Simpson read his paper to the Society, two years had elapsed since the operation, and the patient was then continuing to enjoy the best of health. In the third case, the diseased cervix presented a well marked specimen of Müller's *carcinoma reticulare*. The patient remained well for eight months, but the disease then recurred, and proved fatal fourteen months after the operation. Dr. Simpson's published experience is therefore an encouragement to operate.

A powerful argument in favour of the propriety and rationality of attempting a cure by operation is to be found in the able researches of Dr. Andrew Anderson of Glasgow.[1] He has shown that cauliflower excrescence is "a disease which cannot spread by simple germs, as ordinary cancer is supposed to do; for, in order to its growth, a regularly formed membrane is necessary, and not merely active cells; and this consideration", adds Dr. Anderson, "renders more probable the success of the operation of removal of the tumour with the portion of the os uteri from which it grows." According to Dr. Anderson, "the basis" of the cauliflower excrescence "is a membrane of extreme tenuity, ramifying most complexly, amply supplied with blood, and possessing the power of forming from that blood a whitish 'cell-substance', which is deposited in a layer around it." He conceives that "the white substance which constitutes the bulk of the structure is formed by the membrane as a matrix, and from the blood with which that membrane is supplied, by a change in the corpuscles." He had no opportunity of examining the characteristic "watery discharge"; but he believes that it will be found to flow from the white substance directly, probably in consequence of the bursting of the external layer of cells, they being as quickly reproduced within; that thus a constant drain from the blood is going on, and made more exhausting by occasional actual hæmorrhage when the tumour happens to be congested, or accidentally injured.

It appears, then, from Dr. Anderson's researches, that cauliflower

[1] Anderson (Dr. A.), Edinburgh Monthly Journal, vol. for 1842, p. 885.

excrescence differs from every known malignant tissue in its mode of growth. "It grows *by imbibition from the blood*, but *beyond the capillaries*." This view of the morbid anatomy of the disease, its uniformly fatal issue when left alone, and the comparative success of Dr. Simpson's operations, would induce me, if consulted at a very early stage, unhesitatingly to advise excision, provided the diagnosis demonstrated the growth to be of that description which Dr. A. Anderson has described. If asked at a later period, I would not advise the same course to be adopted, unless the symptoms were, as in the case of Mrs. G., so urgent as to threaten speedy death; and then, we are not only justified in operating, but imperatively constrained to do so. If an operation be decided against, the proper treatment to adopt would, I apprehend, consist in the use of astringent anodyne injections, and gallic acid as a constitutional remedy. Each case will however demand its own special appliances.

The question as to the disease being hereditary I do not now enter upon. I may state, however, that the mother of my patient died from what was described to me as "cancer of the womb".

Essex House, Putney, November 1850.

THE CHARACTERISTIC PECULIARITIES, PATHOLOGY, AND TREATMENT OF RHEUMATISM,

MORE PARTICULARLY AS IT IS FOUND PREVAILING WITHIN THE TROPICS.

By JAMES BIRD, A.M., M.D.

Improved views of the humoral origin of Rheumatism have from time to time arisen, to claim the attention of the profession; and the exclusive opinions of solidism, from the beginning of the present century, have been gradually giving place to that more eclectic and rational system of pathology, which looks not on diseases as confined to particular organs or tissues, but as the manifestations of more general and deep-seated lesions, to be sought for in the abnormal deviations of the blood, and the perverted actions of the nervous system. Among those whose judicious observations have tended materially to improve our knowledge of this subject, the names of Drs. Todd and Bence Jones stand prominently forward, as worthy of honourable mention. There is yet, however, much left for study and analysis in the natural history of the disease, particularly as it is found prevailing within the tropics, among a class of patients subsisting almost exclusively on non-azotised articles of diet. Excepting fever and cholera, there is no disease which proves more fatal to the sipahies of our native army; nor is there any which annually renders so many Native and European soldiers unfit for the active duties of their profession, by placing them on the invalid or pension list. Tropical climates seem to have considerable influence in modifying the character of rheumatism among the people of India; and the completion, in that country, of a truly philosophical investigation into the chemical pathology of this and other diseases, might be attended with useful results, in helping us to ascertain the true nature of the rheumatic diathesis, its modifications

under climate, and the relation of rheumatism to other diseased conditions. In this country, too, the practice pursued in rheumatism is undefined and somewhat empirical; one employing lemon-juice, another colchicum, and a third a purely alkaline treatment, without any explanation of the principles, or differences of diseased condition, on which such opposite systems of treatment are recommended. It is therefore matter for wonder and regret that, with the exception of the late Dr. Malcolmson in his *Essay on Beriberi and Rheumatism*, and Dr. Geddes in his *Clinical Illustrations of Indian Disease*, almost every writer on tropical diseases has passed over, without notice, this prevalent and important complaint. The latter author states, that he found rheumatic cases formed about one-eleventh part of all other complaints admitted; and that, during the five years he was in charge of the Madras European Regiment, 457 cases were admitted; of which, the detailed records of 312, including relapses, and occurring in 160 individuals, formed the subject of his statistical remarks and experience. Regarding the seat of the disease, he observes: "On a general review of the whole, forty-seven individuals are discovered to have been subject, either in their primary or relapsed attacks, to rheumatism, both in the muscles and ligaments; forty-three had those structures affected along with that of the periosteum; twenty-eight and twenty-three had respectively disorders of the ligaments, or of the muscles only; in five individuals the disease was confined to the periosteum; in eight this structure was attacked with that of the joints, and in three with that of the muscles only. In the remaining three, the disease was chiefly of a neuralgic character, attended, in two, with rheumatism of the ligaments and muscles."

In the narrow compass of this paper it would be impossible to enter on a complete consideration of the several points connected with the rheumatic diathesis, its paroxysmal progress, and local manifestation in particular organs: I must, therefore, confine my present observations to—1st. Leading varieties of tropical rheumatism, and the points in which articular rheumatic inflammation differs from simple suppurative inflammation. 2nd. Origin of the rheumatic diathesis, nature of the paroxysmal fever accompanying articular inflammation, and causes which produce them. 3rd. The general principles of treatment.

I. LEADING VARIETIES OF TROPICAL RHEUMATISM, AND THE POINTS IN WHICH ARTICULAR RHEUMATIC INFLAMMATION DIFFERS FROM SIMPLE SUPPURATIVE INFLAMMATION.

Tropical rheumatism presents two principal forms; the sthenophlogistic or acute, and the astheno-cachexial or chronic. The former, in its attack of particular tissues, shews a preference for the compound membranes of a mucous and serous kind; the latter affects the muscular and nervous tissues, and has much of a neuralgic character, accompanied by vitiated nutrition, and wasting of the parts affected. The very acute variety, associated, as in Europe, with pericarditis, or endocarditis, is a form of the complaint seldom presented to observation in India; though cases presenting the ordinary symptoms of heat, pain, redness and swelling of the joints, accompanied by fever, occur both among natives and Europeans. The greater number of such

attacks, however, happen among those who are located in the colder, drier, and more elevated table-lands of that country; while the more common form of the disease, prevalent among the natives, particularly those inhabiting malarious districts, is the astheno-cachectic variety; which, when it assumes the form of periostitis, has all the character of mercurial syphilitic cachexia. This latter has been sometimes named pseudo-rheumatism, though no well founded distinction between it and rheumatic affection of the synovial tissues of the joints has yet been established.

Stheno-phlogistic rheumatism is generally attended by disorder of the intestinal mucous membranes and abdominal secretions, much constitutional disturbance, and aggravation of the fever and pain at night. It is often associated with hepatic congestion and colonitis; but when the phlogistic symptoms are unsubdued, they are accompanied by much destructive irritation and waste of tissues, total failure of the digestive powers, emaciation, loss of strength, pale anasarcous visage, and other signs of cachexia, so that too active or injudicious employment of bleeding, or of the diaphoretic and purgative treatment, must be guarded against. The following are cases of the stheno-phlogistic kind.

Case I. Joseph Fido, engineer of the steamer *Atalanta*, aged 23, was attacked, on the evening of the 8th August, 1838, by extensive swelling and redness of the left knee-joint, accompanied by tenderness of the parts, and inability to move the limb. The inner edge of the knee was most affected, but the whole presented a puffy elastic swelling of the joint, accompanied by slight heat of skin, accelerated pulse, some degree of headache, furred tongue, and a constipated state of bowels, which had existed for some time previous to the attack. Mr. Sproule, the assistant-surgeon of the vessel, repeatedly abstracted blood from the joint by means of cupping-glasses, caused the patient's bowels to be freely acted on by purgatives, and then administered four grains of calomel, with tartar-emetic solution, three times daily, till the gums became slightly tender from the calomel. This result followed in a few days, accompanied by diminished swelling of the knee-joint and disappearance of all cutaneous redness, with a return of the skin's natural temperature. The joint, which was still swollen, remained incapable of motion. Repeated blistering was had recourse to, previous to his admission into the European General Hospital at Bombay, on the 11th of September. At this time, swelling and thickening of the parts surrounding the joint still existed, accompanied by inability of motion. Straps of mercurial plaster were applied around the joint, iodide of potassium in sarsaparilla decoction was given daily, and purgatives, with the addition of colchicum wine, were administered occasionally. Under this treatment the joint soon resumed its natural appearance and power of motion, and the patient was discharged well.

The next is a case illustrating the same disease as it attacks a native of India.

Case II. Body Sing, private in the 18th Regt. of Native Infantry, aged 30, admitted at Kalludghee, 3rd September, 1835. Complained much of pain in the joints of his upper and lower extremities; swelling, heat, and tenderness of the left knee; pulse 120, firm; bowels re-

ported regular; tongue excited. He took an emetic, which produced vomiting of much bilio-mucous matter; he was afterwards bled from the arm to fifteen ounces, without experiencing any relief from pain. The blood drawn was cupped and a little buffy. From the 5th Sept. till the 10th October, the treatment consisted of small doses of calomel with fifteen-grain doses of Dover's powder, administered at bed-time, followed next morning by occasional brisk purgatives, combined with full doses of colchicum wine. After this time, the knee-joint being very painful, accompanied by loss of flesh, and other symptoms of incipient cachexia, the patient was ordered to take half a pint of compound sarsaparilla decoction, with an equal quantity of warm milk, twice daily. On the 28th following, the health was much improved, and the pain and swelling of the knee-joint were greatly lessened. From the 28th October to the 12th December, when he was discharged to perform easy duty, he took three-drop doses of cajeput oil twice daily, and had his left leg and knee-joint firmly bandaged with flannel. Copious perspirations followed the administration of the oil, giving great relief to the rheumatic symptoms, and a small tender swelling, which made its appearance on the sternum, completely subsided at the same time.

Astheno-cachectic rheumatism is so generally associated with arthritic periostitis and constitutional *cachæmia*, that we must beware of employing long-continued mercurial courses for the cure of even its stheno-phlogistic variety, as these are apt to give rise to much derangement of the primary assimilation and to obstinate forms of periostitic inflammation. This caution is particularly necessary in regard to the mercurial treatment of rheumatism among the natives of India, who, from their more general use of non-azotised articles of diet than the European inhabitants of India, possess less vital power of resistance to the destructive metamorphoses of the tissues, and heedlessly employ cold bathing while under the constitutional effect of mercury.

The periostitis which we meet with in such cases affects the head, the vertebræ, or the sternum, and sometimes the shin-bones; but when the cachexia accompanying it proves fatal, either by diarrhœa, dysentery, or hectic, follicular ulceration of the intestines is generally found associated with the other symptoms. The strong constitutional disposition existing in such cases towards wasting decay and ulceration of particular tissues, originates probably in the disproportionate use of farinaceous articles of diet without a sufficient admixture of azotised food; and the extreme irritability and obstinacy of ulcers among the natives of India may be ascribed, I think, to the same cause. There is good ground for concluding that the frequency of periostitis in Indian rheumatism arises from the enervating influence of climate, malarious causes, and a poor vegetable diet; though its occurrence, consecutively to abused mercurial courses and exposure to cold, is observable among well-nourished Europeans unattended by that defective assimilation and rapid emaciation, which accompany it in native constitutions. Such cases, however, have been generally those of seamen who have been exposed to cold and the use of salt diet, and were received into hospital from the ships in harbour. The constitutions of these men manifested slight signs of a scorbutic diathesis, caused by the

salt diet, and by neglect of those measures for keeping the bowels in a healthy state of excretion. Hence the rapid and well-marked utility in such instances of removing the men from ship-board to a hospital on shore, with the use of fresh meat diet, warm bathing, the necessary employment of purgatives, and an allowance of lime-juice and potatoes.

As cachexia advances in cases of this kind, attended by a complication of rheumatic symptoms, the skin, which becomes harsh and dry, is covered by white scales, or papular eruptions, having all the character of obstinate psora. The intimate sympathy existing between the epithelial covering of the intestinal mucous surfaces, and that of the skin, helps us to an explanation of the occasional association of cutaneous eruptions with derangements of the primary assimilation and intestinal mucous surfaces, as observable in the different forms of arthritic complaints. This deranged condition of the digestive organs and skin may be found co-existing in most cases of phlogistic and cachexial rheumatism; but one or other of these has precedence and predominance in the complaint, just in proportion as there exists some original defect in the assimilating power of the one, or the eliminating function of the other.

The intimate relation that subsists between milder and modified degrees of scorbutic *dyscrasia* and the forms of *astheno-cachexial* rheumatism, has of late years been almost lost sight of; notwithstanding that the great and accurate observer, Sydenham, described a species of rheumatism resembling scurvy in its capital symptoms, and requiring nearly the same method of cure; and which he distinguished by the name of scorbutic rheumatism. This species of the disease will be found, under ordinary circumstances, on ship-board, and among European sailors, using in excess salt-meat diet, with little or no admixture of succulent vegetables; as well as among bodies of men, on land, living on farinaceous seeds destitute of anti-scorbutic properties, or on a diet of unvaried character with total abstinence from animal food. Such are the circumstances, aided by extreme aridity or dampness of climate, under which land scurvy prevails among prisoners in the jails of India, and also among bodies of native troops, in particular seasons and localities. The same unvaried farinaceous character of diet, used by many of our sipahies, predisposes them to attacks of cachexial rheumatism. In the eighth volume of the *Calcutta Medical Society's Transactions*, there is an interesting account, by Messrs. Ross and Macnab, of this kind of land scurvy, as it appeared in 1834, among the native troops at Nusseerabad. Many of the cases appear to have been of a mixed scorbutic and rheumatic character; and so closely, says Mr. Macnab, did the excruciating pains of the extremities simulate rheumatism, that, in some instances, the distinction could not well be established; and even when tumefaction took place about the joints or in the periosteum, the difference was by no means distinct. Removal of the patient from the station, and change of air, were attended by well-marked benefit; and the transition from an arid to a milder and more humid state of the atmosphere was followed by amelioration of the malady among the troops.[1]

Case iii. William Collier, baker of the ship *Herefordshire*,

[1] Transactions of the Medical Society of Calcutta, vol. viii, p. 118.

aged 26 years, was admitted into the European General Hospital, at Bombay, on the 8th Dec. 1836, complaining of swelling, pain, and stiffness of the large joints, more particularly the elbows, accompanied by loss of appetite, leucophlegmatic countenance, and tenderness and enlargement of the right tibia. He had been more or less affected, on ship-board, by these symptoms for the three previous months, had gradually lost flesh, and used nothing but friction with camphorated liniment to the swelled joints. He was ordered to take half a pint of compound sarsaparilla decoction, with three grains of iodide of potassium twice daily, along with three ounces of diluted lime-juice, and was placed on the chicken diet of the hospital, with half a pound of potatoes. His health gradually improved; the swelling of the joints, and the tenderness and enlargement of the tibia disappeared; and the patient was quite well by the 2nd of December, twelve days after his admission.

Case iv. James Cleet, aged 30, seaman of the ship *Herefordshire*, was admitted into the European General Hospital on the 7th Dec., 1836, complaining of nearly the same symptoms as the last-named patient, with the addition of some livid spots on the calf of his left leg. He was treated by four ounces of bark infusion, given twice daily, and acidulated with diluted sulphuric acid; used a warm bath at bed time; had the same diet, with an allowance of lime-juice, as the former patient, and was quite well in fifteen days after the date of his admission.

The next case is a still better illustration of the intimate relation between milder degrees of the scorbutic diathesis, and the forms of astheno-cachexial rheumatism.

Case v. John Reid, seaman, government steamer *Atalanta*, aged 26, was admitted into the European General Hospital at Bombay on the 1st Nov. 1839. He had rheumatic periostitis of the head and sternum, accompanied by pyrexia. The pyrexia was subdued by the warm bath, mercury and chalk, with Dover's powder and purgatives. Was soon after attacked by pain in the cardiac region, unaccompanied by any abnormal sounds of the heart. This was removed by looseness produced by the use of antimonial mixture and colchicum, two ounces of lime-juice being allowed him daily at the same time. Subsequently to this, quinine solution was given twice a day, with an anodyne at night; but the periostitis of the scalp returning, accompanied by pain at the base of the occiput, it was thought necessary to omit for a time the quinine solution, to abstract blood from the temples and nape of the neck, and to apply a blister over the cervical vertebræ from the base of the skull. After a time, the quinine solution was resumed with good effect, and the patient was discharged free from pain, and with a recommendation that he should be sent to England, as he was much debilitated and unfit for duty in a tropical climate. A month previous to his admission, he had been discharged from the hospital cured of a somewhat similar attack, accompanied by scorbutic symptoms.

The graduated forms of rheumatism just described derive most of their difference from constitutional causes of distinction, and the less or greater aberrations of the blood from its normal state; but the distinctions of this disease, according to its seat in various parts, though not affording like important grounds for opposite therapeutical prin-

ciples and modes of treatment, are still of utility in directing the mind of the practical physician to important local differences, associated with equally well-marked gradations of the constitutional symptoms which attend them. The chief varieties of tropical rheumatism, founded on such locality, are those divisions of the disease which have been adopted by M. Chomel. 1. Articular rheumatism, or rheumatism of the joints; 2. Muscular rheumatism, or rheumatism of the voluntary muscles; and, 3. Visceral rheumatism, or rheumatism of certain fibrous tissues situated within the splanchnic cavities. The generality of cases belonging to the first form, as met with in the tropics, oftener present symptoms of the mild chronic variety, than of the intense articular rheumatism of European climates; and though attacks are generally ushered in by febrile symptoms, these symptoms are of less severity than in colder climates, and the disease is less mobile in character. Muscular rheumatism, too, though met with in every part of the body, and usually more amenable to treatment than cases of the articular form, is more frequently met with in the loins and muscles of the limbs than in any other part of the sarcous tissues. This is peculiarly a disease of malarious districts, being very prevalent among the men of native regiments when located in such places.

The following extract from my quarterly report, on diseases of the 2nd Troop Horse Artillery, for 1822, then stationed at Kaira, in Guzerat, embraces the leading particulars of this variety of rheumatism, as we meet with it among Europeans. "The patients complained of severe pain in the joints, tenderness of the plantar fasciæ, and sometimes of the bones, or sharp lancinating pain beneath the sternum. There was seldom any swelling of the joints, but the muscles leading to them were painful when pressed, and were affected, in one case, with cramps. The disease appeared to be connected with considerable derangements of the biliary function; but the appetite was not in any case much impaired. Only two patients felt pain from pressure in the region of the liver; but tenderness of the sternum was a common symptom, and there was generally some variation of the stools from their natural yellow colour, indicating more or less derangement in the secretion of bile. All those who suffered from this disease had been much debilitated by intermittent fevers, or biliary affections, in the previous months." In general, articular rheumatism of the tropics is of the mild stheno-phlogistic character, while the muscular variety is of the astheno-cachexial type.

Did time or the limits of this paper permit, I could adduce many interesting illustrations of these several local forms of tropical rheumatism; but I must now proceed to inquire whether the phenomena of this disease be identical with those of inflammation and the phlegmasiæ. While rheumatism sometimes appears with all the phenomena of the phlegmasiæ, such inflammation still possesses a specific character, and is in its nature more symptomatic than idiopathic, manifesting in its progress that the local symptoms proceed from a particular constitutional taint, which gives to them a character distinct from that of simple inflammation. This taint may not always affect the joints, but successively various tissues of the body. The mobility of rheumatic inflammation, or disappearance from one part and appearance elsewhere; its pain, too, the manifestation of a constitutional

cause, being frequently diminished by compression and rubbing; its want of determinate progress and limit of duration; its tendency to periodicity and aggravation at night; its extreme susceptibility of impression from changes in the air and of electricity; and its readiness to return after errors of diet or exposure to cold, are all proofs that simple inflammation does not constitute the disease, but that it proceeds from a specific cause associated with abnormal sensibility of the nerves. Though the disease, therefore, generally presents quite as much the character of the neuroses as of the phlegmasiæ, evidence is not wanting to prove that acute articular rheumatism sometimes terminates in suppuration and purulent effusion into the joints affected. Few as these cases are, they are important proofs of the necessity of attending, in our treatment of this disease, to therapeutic means for subduing both local and constitutional symptoms. M. Bouillaud, in his researches on articular rheumatism, instances cases of the disease terminating in suppuration; and in a late discussion on this subject, before the Academy of Medicine, M. Andral brought forward the case of a woman, (who died at the Charité in Paris), whose shoulder-joints, after a severe attack of pneumonia, had been the seat of simple and complicated acute rheumatism. The patient, who was aged, had died in about eight days without an apparently sufficient cause. The interior of both scapulo-humeral articulations contained homogeneous pus, similar in character to that which is the result of phlegmonous inflammation. The surfaces presented innumerable minutely injected vessels, forming the closest network, except on the articular cartilages, where this injection was but slightly marked. The bursæ about the joints were also filled with pus. The parts external to the joints, as the muscles and ligaments, were in their normal condition.[1] In other cases, lesions of the synovial membranes, cartilages, and extremities of the bone, appearing to be of an inflammatory nature, have been found; but as these are not constantly connected with the rheumatic affection, they are not to be regarded as its anatomical cause, and must rather be considered as an effect.

II. ORIGIN OF THE RHEUMATIC DIATHESIS, NATURE OF THE PAROXYSMAL FEVER ACCOMPANYING ARTICULAR INFLAMMATION, AND CAUSES WHICH PRODUCE THEM.

Rheumatism may be generally considered a result of pre-existing lesion of the assimilating and excretory organs of the body; which, on the application of cold, errors of diet, intoxication, malaria, and like exciting causes, gives rise to that anormal change of the blood which constitutes the rheumatic diathesis. The sudden or continued influence of damp cold air, producing a powerful impression on the skin and nervous system, may in European rheumatism be considered the first link of the chain of changes connected with the generation of the *materies morbi* in the blood. The equilibrium of healthy nutrition is disturbed, the tissues cease to appropriate true nutritive materials, the assimilating functions of the stomach and collatitious viscera are deranged, and the eliminating excretory action of the liver, skin, and kidneys, further impaired or suspended, so as to admit of effete

[1] London Medical Gazette, vol. xlv, 1850, p. 304.

and imperfectly oxydized materials reverting into the circulating fluid. The two former cease to remove from the blood the healthy proportion of carbonised principles, and the constitutional disturbance following this state is still further augmented by the azotised products of secondary assimilation being retained in the system, as indicated by the deposition from the urine of various lithates after nocturnal rheumatic paroxysms. In place, therefore, of the lungs and their supplemental organs, the liver and skin, eliminating, in normal proportion, the non-nitrogenous and azotised elements in the form of carbonic acid and urea, there is now a morbid development of cutaneous perspiration, containing lactic acid, with imperfect excretory functional power of the kidneys. The latter having ceased to remove the normal proportion of urea from the system, excrete in its place uric acid and the urate of ammonia, or the imperfectly oxydized constituents of the body.

It may naturally be asked, is the blood altered previous to the appearance of swelling and local inflammation of rheumatism? Though this be a question most difficult of solution, even as regards other inflammatory diseases, the disposition of the circulating fluid to an altered abnormal condition in this disease, usually precedes the development of its local symptoms. We must admit, however, that cold and other causes occasionally produce rheumatism in constitutions little or not at all disposed to the disease, though the reverse be usually the case. In those instances the altered condition of the blood follows the development of the local affection; but, in either case, the physiological opinion of Simon, that the metamorphic power of the blood globules is increased, affords the best explanation of the chemical phenomena of rheumatism; as this heightened metamorphosis of the blood at once accounts for the greater relative formation of fibrin, and the progressive diminution of hæmato-globulin, as they occur in rheumatic fever and its consequences. The natural tendency of rheumatism is to *anæmia*, and to the production of phenomena, connected with a diminution of the blood globules, as lately prominently noticed by Dr. O'Ferral, in his observations on rheumatic cases with endocardic complications; where, after the employment of depletion and mercury, a cardiac bruit, different from that which originally presented itself, continued to persist, notwithstanding the steady employment of means for subduing inflammatory action.[1]

That morbid condition of the blood, which constitutes the *rheumatic dyscrasia*, occurs in all cases where the circulating fluid either becomes deteriorated by the absorption of foreign poisonous matter, as in gonorrhœa, and in certain exanthematous diseases, accompanied by primary and secondary symptoms; or by the reversion into the blood of increasingly morbid secretions, as in uterine affections that give rise

[1] One of the most important bearings of improved physiological knowledge is on pathology and the primary element of diseased condition; and though our facts on the subject of blood-diseases be yet limited and undetermined, there is much reason for the belief, that the healthiness or unhealthiness of the blood itself depends on the greater or less perfection of its cell-development, and that wherever its colouring matter, *hæmatin*, is defective in quantity, or depraved in quality, it proves incapable of fixing the oxygen of the inspired air, and thus gives rise to perverted nutrition of parts, defective calorification, and ultimate anæmia.

to those diseased conditions, and which, though now fashionably treated as local disease by caustic and other like applications, are often, indeed, symptomatic of an acquired state of constitutional dyscrasia. Dr. Geddes, in his excellent clinical illustrations of Indian disease, observed that neither heat, rain, nor cold, appeared to have any reference to the prevalence of rheumatism; but that, in individuals possessing constitutional peculiarities, pseudo-syphilitic virus gave a tendency to the occurrence of rheumatic inflammation, aggravated in some cases by the exhibition of mercury. Impaired primary assimilation, defective clothing, and malarious locality, or whatever other causes, having a tendency to render defective normal excretion, seem to materially aid the absorption of such foreign matters, and to produce, in India, rheumatic cachexial affections of the utmost intensity. Such defective excretion gives rise to the undue production of lactic acid in the body; depending, as Dr. Bence Jones has shown, in some of the stheno-phlogistic cases, on excessive ingestion of azotised food; and, in those of an opposite kind, on the introduction of an insufficient amount of oxygen into the system, and on defective elimination through the excretory organs. In both cases, the urea, which is the produce of the molecular decomposition of the muscular and azotised tissues, is partly converted into uric acid and urate of ammonia, and appears in the urine as a fawn-coloured lateritious sediment.

The anatomical seat of rheumatism is peculiarly confined to the fibro-serous tissues, including the articular capsules, cellular tissue, mucous follicles, synovial glands, the interior ligaments of joints, the muscles and tendons, the dura mater as reflected on the medulla oblongata and spinal cord, the pleura, the peritoneum, and nerve tubules. The localized manifestations of disease are accompanied, according to age, temperament, and previous habits, by almost opposite conditions of the blood, states of *hyperinosis* and *hypinosis;* which differences of constitutional cause give the rheumatic swelling of the joints more or less the character of ordinary inflammation. The local swelling of stheno-phlogistic rheumatism differs from ordinary inflammation in having more a character of irritation than the latter; but, according to the researches of M. Andral, agrees with it in this, that the fibrin in the blood increases from two and a-half or three to as much as ten parts in one thousand, oscillates in the sub-acute form between four and five, and returns to the natural standard in well marked chronic cases. This state of *hyperinosis* is, however, rather relative than absolute, being accompanied by a corresponding diminution of the red corpuscles; which, as Simon supposes, are wasted in the metamorphic production of the fibrine. The following table exhibits the relative increase of fibrin to the ratio of *hæmato-globulin*, both in rheumatism and scurvy, as compared with healthy blood, by which a well-marked analogy between the conditions of rheumatic and scorbutic *dyscrasia* is at once indicated. *(For Table, see next page.)*

Rheumatic paroxysmal fever, which is associated with much irritation, may be considered the manifestation of the rheumatic diathesis in the various tissues, brought on by the action of cold on parts, so that the condition of healthy nutrition is suspended, and hyperæmia with swelling, or inflammation of a destructive kind begins. The pain is accompanied by numbness, and the redness and swelling are

often slight in comparison to its degree. A specific anormal change of the blood, and a greater alteration of the nervous force than occurs generally in simple inflammation, sometimes amounting to anæsthesia of the parts, or accompanied at others by greatly increased nervous sensibility, seem to mark the condition and progress of rheumatic inflammation. In one remarkable case of a seaman named John Brickle, aged 25, who had remained for four hours together under water while in the Persian Gulf, the rheumatic symptoms and tenderness of the voluntary muscles were preceded by well-marked peripheral anæsthesia. This patient was cured by an almost daily use of warm bathing, diaphoretics and purgatives, with friction and light flannel bandages to the limbs. The change of air, too, from the Persian Gulf to Bombay, exerted no small influence in improving the general health and removing symptoms of disease.

The irritative fever accompanying local rheumatic affection, sometimes precedes or simultaneously occurs with the symptoms of pain, stiffness and swelling of the joints; sometimes it is ushered in by chills, followed by heat of skin, frequency of pulse, and other pyrexial symptoms. More frequently, however, and particularly in malarious districts, the febrile symptoms are of an obscure hectic kind, presenting no very definite character; being marked, however, by nightly insomnia, aggravation of the pain, restlessness, and slight morning perspirations, which seldom bring much relief from the painful affections of the joints and muscles. The patients, when unrelieved, continue to lose flesh and strength, their muscles become attenuated, and their skins covered by various kinds of eruptions, as mentioned in the previous section. In such cases, particularly those of natives of India, change of air, and relief from the night watches and duties of a soldier, are followed by complete restoration of the persons to health, without any therapeutic means beyond a return to the diet and air of their native villages, with complete exemption from labour and fatigue.

We learn from Dr. Geddes's statistical experience of this disease in

India, that fever existed in less than one-third of his cases; was as common in relapses as in primary attacks; and was not more confined to one local variety of the disease than another. In one half of the patients who had fever, it existed only for a short period, and was, in the remainder, either slight or irregular. According to my own observation, there is generally an apparent disposition in rheumatic fever, like that accompanying exanthematous diseases, to subside after the local appearance of diseased action in the tissues. Though the febrile symptoms and pain will often be found to abate and increase irregularly, without any well-marked degrees of severity between the proportion of the local and the constitutional affection.

III. TREATMENT.

The general therapeutic principles to be followed in attacks of tropical and European rheumatism, are—1. to subdue constitutional irritation and fever by bleeding, narcotics and refrigerants. 2. To eliminate from the system the retained cholæic elements, and other excrementitious matters of the blood, which render the urine acid, and occasion its lithic deposits. 3. To restore the condition of normal nutrition by suitable diet in the stheno-phlogistic kinds; and by iron, cod-liver oil, and tonics, when the rheumatic symptoms are associated with *cachemia*. 4. To subdue local symptoms of swelling and pain by leeching, cupping, and blisters, followed by anodyne applications, or local anesthætics.

In order to fulfil the first indication, which is the principal and leading one, in cases of the stheno-phlogistic kind, much professional discussion and difference of opinion have arisen, regarding the efficacy and propriety of general bleeding, as one of the means. The extent to which this remedy may be usefully employed, will depend much on the youth and naturally plethoric constitution of the patient, the inflammatory character of the local affection, the severity and tonic nature of the accompanying fever, and the purity and bracing influence of the air to which the patient has been habitually exposed. The degrees of fever are found to correspond generally to the coldness and purity of the air in which the patient has lived, the azotised richness of his diet, and the proportionate *hyperinosis* of the blood accompanying good air and rich nourishment. In a general inflammatory diathesis, therefore, the propriety and efficacy of general bleeding are fully established by our own experience, and recommended by a host of unexceptional authorities. But the natural tendency of rheumatic inflammation and fever being to produce anæmia, we must not be too prodigal in wasting the nutritive resources of the constitution; and should be guided in repeating the bleeding, according to the quantity and inflammatory firmness of the blood-clot, and the effect which the first bleeding may have had in subduing irritation and mitigating fever. The same extent of general blood-letting, that might be useful to the temperate and well-fed inhabitants of cold salubrious localities, would be highly injurious to the nervous irritable bodily habits, of those addicted to excessive beer drinking and other dissipated practices. The same quantity of blood, then, abstracted to cure quickly the plethoric mountaineer of Scotland, would endanger the life or render tedious the convalescence of an inhabitant of London, breathing an atmo-

sphere deteriorated by sulphuretted hydrogen. The necessity, too, of general bleeding in tropical rheumatism is rather an exception than the rule, as might be expected from the comparatively mild character of its fever and inflammatory symptoms.

To carry out further this indication, after a moderate bleeding, recourse may be had to ten-grain doses of nitrate of potash, given along with small doses of tartarized antimony and citrate of potash, three or four times a day, in the form of effervescing draughts. Or the nitrate of potash may be combined with nitrous ether and other diuretics; the intention in either case being to subdue heat and irritation, by restoring the normal excretory functions of the skin and kidneys. The utility of nitrate of potash seems dependent on its power of diminishing the plasticity of the blood and suspending the metamorphic disposition of the blood-globules to produce fibrin. Under its use, the specific gravity of the urine is increased, this being a medicine which possesses the power of eliminating urea and other compounds of lithic acid from the system. Such power is probably increased by the combination of nitrate of potash with other alkaline compounds, as the citrate and acetate of potash, which are converted into carbonates in the course of the circulation. All such means, however, prove refrigerant by subduing the heat and irritability of the body; and the effect of such may be greatly increased by the addition, at bed-time, of anodynes, either opium or aconite.

Of medicines best adapted to carry out the second indication, calomel and Dover's powder at bed-time, followed, next morning, by a solution of sulphate of magnesia in compound senna infusion, with the addition of an alkali and colchicum, will be found among the most useful. Much misapprehension regarding the beneficial therapeutic action of the latter medicine seems to exist, some deeming its chief efficacy consists in its power of eliminating urea and uric acid from the system; while others deny to it any efficacy in subduing symptoms of true rheumatism. It is chiefly useful in cases of the acute disease, accompanied by a foul loaded tongue, biliary derangement, and intestinal mucous accumulation. Both my Indian and European experience have convinced me of the fact, that without its purgative effect being induced, the urinary secretion is seldom so much increased in quantity as to bring with it any considerable relief of rheumatic symptoms. The most beneficial mode of administering it in India is to give the wine of colchicum, twice or thrice a day, in a weak solution of tartarised antimony, along with liquor potassæ, and tincture of the hydrochlorate of morphia. Free action of the kidneys and skin is thus kept up, and the feverish frequency of the pulse reduced; but, even in such a case, the use of purgatives, and the elimination of the biliary secretion, must not be neglected or lost sight of. Where diarrhœa, or the purgative effect of colchicum is established, there the amount of urea and uric acid in the urine appears to be diminished; these compounds being eliminated, as would appear by the intestinal evacuations. Dr. Boecker, in a late minute examination of the action of various medicaments, with reference to the changes produced by them in the constituents of the urine, the exhalations of the lungs, and the blood, found that, contrary to the general opinion of pharmacologists, the use of colchicum produced but slight diuretic action,

and had very little effect on the constituent parts of the urine. During its employment, the activity of the skin and lungs, in exhaling carbonic acid, is considerably augmented, and after a time its effect in causing an augmented secretion of bile becomes apparent; the melanotic blood globules, which are unable to combine with the oxygen of the air, being destroyed in the hepatic system, afford materials for an augmented secretion of bile. The result of his analyses, thirteen in number, on the action of colchicum, and its known utility in rheumatism, seem to bear strongly on the truth of the opinions expressed as to the pathological nature of this disease.

The employment of calomel, with a view of obtaining its full purgative effect in cases of the stheno-phlogistic variety, should be more steadily pursued to carry out this indication than the plan of giving it with opium, in order to obtain its constitutional effect. From its special action on the biliary organs, it is in Indian rheumatism an invaluable remedy; and in this country too, when properly administered, in aid of colchicum and other purgatives, will be found of much utility, by depurating the blood, through increased biliary secretion, in those hypercarbonised states of the system associated with the disease in many of those cases met with in London. The practice of mercurial fumigation, as successfully used both in this country and in India, proves useful by increasing the elimination from the skin, and restoring the cutaneous functions to a normal state. The same result may be partially secured in both varieties of the disease, by means of warm bathing, warm clothing, and friction of the surface.

The third indication has more immediate relation to cases of the astheno-cachexial kind than to those of acute rheumatism. The impaired state of the digestive function being so intimately associated with the origin and progress of the rheumatic constitution, it is of much importance, while carrying out the second indication in acute varieties of the disease, that due attention should be given to the diet of the patient, which must be diluent and of easy assimilation. In the early stage of disease it should consist of gruel, thin arrow-root with milk, or weak broth; and if beef-tea be allowed, it may be given with the addition of twenty or thirty drops of liquor potassæ; the alkali serving to neutralise the lactic and other acids which accumulate in the stomach along with diseased mucous secretions. As phlogistic symptoms, even in the worst examples of acute Indian rheumatism, are associated with much destructive irritation and waste of tissues, a too active or injudicious employment of the diaphoretic and purgative treatment must be avoided, as it will both derange the primary and secondary assimilation. Such derangement is marked by emaciation, loss of strength, pale anasarcous visage, and other signs of cachexia; and as the early appearance and rapidity of such symptoms are most remarkable in persons inclining to the leuco-phlegmatic temperament, the treatment for carrying out the two previous indications should not be such as makes too great a demand on the resources of the constitution. When cachexia appears we must have recourse to bark, sulphate of quinine, preparations of iron or iodide of potassium, all of which operate beneficially on the constitution, by improving the tone of the organs of primary assimilation, modifying the nutrition of the tissues, and increasing the *hæmatin* of the blood. A combination of

these several remedies may be necessary, according to the nature of particular cases; and where iodide of potassium, if given alone, would utterly fail in relieving symptoms, it may be usefully employed in combination with the decoction of bark or sarsaparilla, or extract of taraxacum; by which the double effect of healthy cutaneous action, and increased elimination by the kidneys, may be generally secured. The iodide of potassium must not be given in large quantities, but along with it laxatives are as essential as in using colchicum. In many such cases, the compound decoction of sarsaparilla, to the extent, at least, of half a pint twice daily, with an equal proportion of warm milk, has been found to be of much utility in promoting the nutrition of the tissues, and bringing back healthy cutaneous action. The extract of sarsaparilla in pills, with resin of guiacum and sulphuret of antimony, may be given advantageously with the same object; care being taken to supply the patient with light easily digested elements of nutrition. Among such elements we may mention cod-liver oil, which in two cases, when prescribed in this country, proved of much benefit. One of these was a case of excruciating pericranitis, affecting the aponeuroses of the cervical vertebræ, and accompanied with neuralgia of the superior maxillary branch of the fifth pair of nerves; the other was hysterical neuralgia of the intercostal muscles. In both cases counter-irritation was employed by means of a liniment of oil of turpentine with pyroligneous acid over the pained parts; and, in the former, the oil was given along with the extract of aconite at bed-time.

The last and fourth indication is to employ remedies suited to subdue the pain and swelling of the local affections. If such are of a muscular kind, strongly stimulating terebinthinate liniments, warm fomentations, and shampooing of the parts, will be found beneficial in relieving pain; but in some cases, such was its severity and persistence, that the patients were relieved by nothing except the abstraction of blood from the parts by means of cupping-glasses. When the joints suffer, and are much pained and swollen, we found no local applications more useful than leeches and repeated blisters to the parts. If the latter be employed, the blistered surface may be dressed with an ointment containing small quantities of the hydrochlorate of morphia, or extract of belladonna. The application also of a wet bandage, saturated with a lotion of camphor mixture, wine of colchicum, and tincture of the hydrochlorate of morphia, covered over by cotton wool and a piece of spongio-piline, to prevent evaporation, will be found of much utility. Others have of late recommended for the same purpose a chloroform lotion, or one of Dutch liquid, stating such to be of great utility in relieving the pain and swelling of the joints; but though we have had no experience of their efficacy, they appear well calculated to fulfil the same intentions as other like remedies which have been long in use. More might be said as to the degree of efficacy of special remedies; but as we place little faith in such, when used without discrimination, we defer their consideration to a more fitting opportunity, the great object of this paper being to delineate the leading characters of rheumatic disease, and the therapeutic indications most applicable to each.

Hyde Park Square, February 6, 1851.

ON THE DIAGNOSIS, PROGNOSIS, AND TREATMENT OF SYPHILITIC ERUPTIONS:

WITH ESPECIAL REFERENCE TO THE USE OF MERCURY.

By THOMAS HUNT, Esq., M.R.C.S.Eng.

DIAGNOSIS OF SYPHILITIC ERUPTIONS.

It is very important to ascertain whether an eruption be syphilitic or not. But this investigation has nothing to do with the distinction between papules and scales, pustules and tubercles; for the poison of syphilis is capable of producing almost every form of eruption. Neither is it wholly a question of colour. The copper-colour, so strikingly characteristic of venereal affections of the skin, is by no means invariably present; nor is every copper-coloured eruption syphilitic in its origin, the hue of the affected portions being materially modified by the natural complexion of the patient. The diagnostic signs of syphilis do not lie on the surface, although the first glance frequently excites well-grounded suspicion. We must appeal to the history rather than to the hue, for evidence of the origin and nature of the disease.

Syphilis is well known to affect the tissues in a certain order; and there is often, but not always, much regularity in the time. Usually, there is first a primary sore, then a swollen absorbent gland, afterwards an eruption of maculæ, followed by an ulcer in the throat affecting the tonsils or velum, or, in other cases, the tongue or lips. The periosteum then becomes inflamed, and a node appears; subsequently the iris is affected; then a secondary eruption on the skin appears, frequently scaly or tubercular, particularly in the palms and soles in the form of lepra, and affecting the genitals and nates in the form of condylomata. At length the cartilages and bones of the nose, face, skull, or other parts, become carious.

When a patient has contracted syphilis originally, and appears before us with a suspicious eruption, we shall generally find upon inquiry, that some or all of the above-mentioned parts have been affected, usually in the order which has been described. When, however, the disease is hereditary, the links of the chain cannot be so clearly traced, and the diagnosis may be difficult. Here, if we can gain any satisfactory knowledge of the health of either parent, it may materially assist our judgment. The eruption should awaken suspicion if it be copper-coloured, and if there be a tendency to ulceration; particularly if the ulcers burrow under the skin, and are partially covered with dull copper-coloured bands of integument. It may likewise be observed, that syphilitic eruptions rarely itch intensely, and as seldom assume a form of active inflammation.

In investigating the nature of venereal eruptions, we may easily be led astray. Various in their form and hue, and not less so in their degrees of severity, they have been described by authors under different names. Hunter wrote of "diseases resembling syphilis": Abernethy wrote of "pseudo-syphilitic diseases": modern writers distinguish between syphilitic and "syphiloid" diseases: Carmichael describes four kinds of syphilitic disease, both primary and secondary; and some of the French surgeons take similar views.

There are, however, many reasons for the belief, that, in this country at least, there is but one syphilitic poison; and that the mischief which this poison may effect depends, in individual cases, not so much on the intrinsic virulence of the poison itself (for of this we can know nothing), as upon the susceptibility of the patient. Some persons cannot be inoculated with it at all; in others it produces only a primary sore; in many it establishes a formidable disease; and a few are absolutely destroyed by it.

The most perplexing difficulties met with in modern practice, connected with the diagnosis of venereal affections, appear to me to arise from a too hasty adoption of the theory, that *mercury is capable of originating diseases similar in character to the secondary forms of syphilis.* Against this dogma, which, so long as it prevails, must necessarily involve the subject in a labyrinth of difficulties, from which there is no escape, I must beg most earnestly to protest, for these reasons:

I. Symptoms resembling syphilis are never observed to result from the use of mercury in cases in which syphilis has neither been previously contracted, nor inherited. No practice is now more common than the exhibition of mercury for various forms of inflammation affecting many of the organs or tissues. Mercurial treatment has, in fact, to a great extent, taken the place of depletion, and is very frequently pushed to ptyalism; and yet, to whatever extent the gums, or the salivary glands, or the bowels, become affected, we never find eruptions or ulcerations resembling syphilis, produced by this treatment. The cheeks and the gums, the lips, the throat, and the tongue, may all become the seat of mercurial ulceration; but the ulcers do not resemble those of syphilis. They are more superficial, less persistent, usually healing when the mercurial irritation subsides; and they never resemble syphilis in affecting distant parts in a certain order. In these and other respects they bear no resemblance whatever to syphilitic affections; and when the system is really free from lues, the difference between these mercurial ulcerations and the sores of syphilis, must be as obvious to the most superficial observer, as is the distinction between the *eczema mercuriale* and the *lepra syphilitica.*

II. The morbid effects of mercury are peculiar, and well-defined; and, with the exception of the ulcerations above described, do not even approach in character any form of syphilis; neither do they exhibit the slightest similarity to that disease. They are as follows: sore gums, salivation, loosening of the teeth, diarrhœa with griping, dysentery (or green mucous evacuations in children), extreme depression of the nervous system, accompanied with trembling of the limbs, infirmity of purpose, an undefined dread of evil or danger, with pusillanimity of mind, dyspepsia, rheumatism,[1] *eczema mercuriale,* etc.

III. The occasional aggravation of syphilitic disorders, under the administration of mercury, may be rationally explained, and fully accounted for, without supposing it capable of originating a chain of symptoms, the character of which (if not the full development) had been established in the system long before the administration of a grain of mercury. The mode in which mercury, when used in excess,

[1] Rheumatism induced by mercury occasionally throws out nodosities in the neighbourhood of joints, but these are not easily confounded with the venereal node.

aggravates the syphilitic action, will be hereafter explained, without adopting the lame and impotent conclusion, that the remedy is capable of producing a disease similar to that which it cures,—a conclusion which has always appeared to me to resemble more the visionary subtleties of homœopathy, than the sober realities of medical science.

PROGNOSIS OF SYPHILITIC ERUPTIONS.

Syphilitic eruptions, like other forms of lues, generally discover, if left to themselves, a tendency to persist (with occasional intermission) through life; and they may be transmitted from either parent to the children.

In a few cases, a spontaneous recovery appears to take place; and, in many, the eruption will disappear for a time under alterative treatment. But it will now be attempted to show that the spontaneous recoveries from syphilis are apparent only, not real.

There is no disease, the destruction of which it is so important to ascertain with certainty, as syphilis. An error here may not only spread unhappiness and desolation over the prospects of married life; but it may affect the health of the next generation. It is therefore impossible to exaggerate the value of well-considered and well-founded opinions on a subject which has been too much regarded as one of mere theory and speculation. The popular belief on the subject is strong, and calls loudly for attention. So anxious, and so properly anxious, are young men to know if, having once suffered from syphilis, they may safely marry, that there are few cases of monomania more common than *imaginary* lues; and the imaginary disease is far more difficult to cure than the real. One reason of this may be found in the unsettled state of medical opinion and the uncertainty of the prevailing mode of treatment.

The *vis medicatrix naturæ* is observed to relieve the system of certain morbid influences or agents, in one of three ways: by elimination, by decomposition, or by tolerance. Under the two former processes, the disease may possibly be cured; but, under the latter, it is only tolerated, or latent. We have no proof that the act of elimination ever occurs spontaneously, or otherwise, in lues venerea; we do not even observe an abortive effort to expel the poison, as occurs in primary syphilis, gonorrhœa, cholera, diarrhœa, diabetes, etc. Neither is there any reason to believe that the poison is ever spontaneously decomposed or neutralized.

The spontaneous recovery from syphilis, when it does occur, appears to be nothing more than a recovery *by tolerance*, consisting merely in the temporary abeyance of the diseased action, excited by the presence of a poison to which the system has at length become habituated and reconciled for the time. This theory of tolerance is in perfect harmony with all the analogies of natural history, physiology, and pathology. The well-known fact that many mineral and vegetable poisons, such as antimony, mercury, tobacco, and opium, become comparatively harmless by long usage, losing their toxical powers as the system becomes habituated to their influence, would sanction the anticipation that certain *animal* poisons also would become inert from the influence of time and habit: and so in fact we find it. An infected couple, both originally labouring under gonorrhœa, may cohabit until all symptoms

of disease in both of them have vanished. Yet they are both capable of communicating the disease to a stranger. John Hunter relates several cases of this kind, showing that a woman, without any new infection, and without any symptoms of disease on her own person, may communicate gonorrhœa to one man, and not to another; and he was of opinion, that the capability of communicating the disease is sometimes the only criterion of a woman having it herself. The late Mr. Hey, of Leeds, was of opinion that a person may infect another with the lues venerea after all symptoms of the disease have disappeared. And if a doubt may be entertained of the nature of the disease on which these opinions are founded, there is abundant proof in the history of syphilis, of its capability of existing in a latent form, as in the well-known circumstances attending the disease at Lisbon during the Peninsular war. At the time when our troops were stationed in that city, the disease existed among the inhabitants in so mild a form, that no mercury was necessary for its cure; and the dancing girls, from whom our soldiers were infected, were well enough to pursue their avocations on the stage without inconvenience. Yet the disease which they communicated to our officers and men proved to be so terrible a form of syphilis, that it was called the "black lion". It produced phagedenic or gangrenous ulceration of the genitals, and horrible mutilations. It was the opinion of some of the army surgeons, that this was a new disease, or at least a form of syphilis of unusual malignity. It is, however, much more rational to look upon it simply as syphilis, so well tolerated by the inhabitants as to become almost latent, but malign in its effects upon the soldiers from the exhausting influences of fatigue, excesses, and a new and sultry climate. This is quite conformable with the fact, that syphilis generally proves a severe disease upon its first breaking out in a country. In England it is certainly much less formidable than it once was. Less mercury will cure it, and it occasionally wears itself out; but it is syphilis still, and its milder forms are often as treacherous as they are transient. A latent virulence lurks under the mask, which may burst out destructively when least expected. For this power of tolerance has its limits. It is limited to certain persons, to habits of life, to conditions of health, to climate, and sometimes to a generation. Thus, sometimes, syphilis may be almost latent in the parent, but severe in the child. A mother may have no symptoms of syphilis in her own person, but may have a succession of still-born children all poisoned *in utero*, or born alive, covered with maculæ, and falling early victims to the disease. A father, in whom lues has become tolerated and latent, may beget a diseased child, who shall, if weak or scrofulous, suffer more than the father. Spontaneous recovery from syphilis is, therefore, in many cases, perhaps in all, an appearance, not a reality.

TREATMENT OF SYPHILITIC ERUPTIONS.

Alterative Treatment. The alterative cure of secondary syphilis, sanctioned as it is by the practice at some of the London hospitals, is probably of the same nature as the spontaneous recovery. Though the anti-syphilitic virtues of Plummer's pill, sarsaparilla, guaiacum, iodine, arsenic, and the mineral acids, are very questionable, these medicines evidently have the power of rendering certain subjects

tolerant for a time at least, of certain forms of secondary syphilis. These agents will bring about the healing of ulcers, the dissipation of eruptions, and the reduction of periosteal swellings; and under this treatment, combined with a regulated diet, scores of patients, perhaps hundreds, are annually dismissed from our hospitals, apparently free from every vestige of disease. The Plummer's pill, although it contains calomel, does not appear to act mercurially, the sulphuret of antimony modifying its action. Indeed, the specific effects of mercury are not apparent; this treatment, therefore, is non-mercurial, and yet patients appear to recover under it. But do they really recover? Do they not frequently return again and again to the same hospital, or to some other hospital, and when again discharged, apparently cured, does it not frequently happen that the first exposure to the effects of intemperance, want, or cold, induces a relapse of the disease? Or, if it be tolerated for life, so that it does not re-appear in the person of the patient, is the wife safe; or, more especially, are the children of the patient safe? The question admits of great doubt. A large proportion of the cutaneous diseases met with in every station in life, are syphilitic. That a man can, without infecting his wife, transmit to his children a syphilitic taint, is an established doctrine. Several cases of this nature are related by the older writers on surgery, and by some of modern date. Several, also, the validity of which no scrutiny can impeach, have occurred in my practice. I have seen syphilis in infants and in children of all ages, whose fathers had married after the non-mercurial treatment of the disease had effected an apparent cure. After marriage (in some cases several years after), secondary eruptions made their appearance. These were treated mercurially, and the result was most instructive. The wife escaped, as did also the children begotten *after* the mercurial treatment of the father; but the children begotten *before* the mercurial treatment were infected. In one instance, the child suffered more than the father. The father had psoriasis plantaris in a mild form; the child, a girl of ten years of age, had iritis, sores about the nostrils, and a scaly eruption on the scalp. All these diseases, together with that of the father, yielded to active mercurial treatment, and to no other; iodine, sarsaparilla, and other remedies of that class, having proved perfectly inert. Several children, begotten and born after the mercurial treatment of the father, were perfectly healthy, nor was any trace of disease to be found in the mother. In another striking instance, a married man contracted syphilis. The primary sore readily healed under simple treatment. Secondary symptoms appeared, which ultimately yielded to active mercurial treatment. In the interval between the healing of the primary sore, and the subsequent mercurial treatment, a female child was begotten. This child was born apparently healthy, but, as she grew up towards womanhood, suffered from sore throat, scaly eruptions, sores about the nose, and other unequivocal symptoms of syphilis. Subsequently to the mercurial treatment of the father, several children were begotten, but not one of these has been affected. And two elder children, born before the father contracted syphilis, have been also entirely free from the disease, together with the mother, who was fortunate enough to escape infection in the first instance.

Nothing is more common than for middle-aged men and women who are afflicted with secondary syphilis, to deny that they were ever affected with a primary sore; sometimes admitting that they have deserved to contract the disease, but denying that such has actually occurred. Assuming that some of them report falsely, common sense claims a certain proportion of these cases as cases of hereditary syphilis, breaking out for the first time in middle age in the form of secondary symptoms.

In the instances which have fallen under my notice, I have generally found alterative treatment useless, and mercury all-sufficient; and the conviction has been more and more forced upon my mind, that the non-mercurial treatment of secondary syphilis may be generally regarded as an inefficient and ineligible practice; inefficient as regards the patient, and ineligible as tending to infect large masses of the community with hereditary syphilis. The disease may be, and often is, mild in its hereditary forms, and it may possibly wear itself out in a generation or two; but this by no means always happens. It aggravates the strumous habit when it happens to come in fellowship with it; and probably is at the foundation of many cutaneous and cachectic disorders, the character of which is undefined and unsuspected. One cannot, therefore, but deprecate a practice which allows the blood to remain vitiated and tainted, from generation to generation, with the presence of an animal poison, which we have, in most cases, the power of destroying at once and for ever.

Mercurial Treatment. The prevailing objections to the use of mercury in syphilitic diseases may be thus summed up: 1, That it occasionally produces lesions more formidable than the disease for which it is prescribed; 2, That its use is not generally necessary to their cure; 3, That besides being unnecessary and injurious, it often proves inefficient and inert.

That there is much of real truth in these objections, no practical man can deny; but there is likewise much fallacy. For as these diseases, in their secondary forms at least, rarely get soundly and permanently well without mercury, it may be said to be generally necessary to their cure. And if rightly and vigilantly administered, it is generally successful. But both its safety and its success will be found to depend very much on its *mode of administration*, by which term is intended to signify something more than its *mode of introduction* into the system; for this, except in peculiar cases, appears to be of little consequence.

Our success in administering mercury may be very much limited by erroneous views of its mode of action. The mineral and the disease have been regarded as two antagonising poisons; the poisonous influence of the mineral counteracting that of the disorder, by setting up in the system a morbid action of a different kind, and incompatible with it. On this theory it would appear that the more disastrous the effects of the medicine, short of the actual destruction of life, the more perfect would be the safety of the patient. The more he is poisoned by the mineral, the less would he be poisoned with lues. And in the event of the disease becoming aggravated by the severity of the mercurial course, it would be necessary for the truth of the theory, to hold, that the original disease having been vanquished by so much

mercury, the existing symptoms must be the symptoms of a *mercurial disease.*

The true theory is probably the very reverse of this. It is very doubtful whether any real advantage is derived, in any case, from the morbid effects of drugs. Disease may succumb in spite of such influence, but not in consequence of it. If a poisonous drug is allowed to do mischief, it has probably been given in excess. A smaller quantity would have accomplished our therapeutical purposes, not only as well, but probably more efficiently. It is in the right dose of a medicine that its real value consists; and too much study cannot be given to this all-important point. As a general rule, the doses in which we are accustomed to exhibit poisonous remedies, are perhaps not only large, but injuriously excessive.

Mercury belongs to the class of mineral tonics, which, in excessive doses, become irritants, and, in large doses, poisons. Its tonic action ceases when irritation is excited in the tissues. In order to avail ourselves of the full benefit of tonics, our attention must constantly be directed to their special properties and peculiarities of action. There is in the organic system an inherent tendency to health. Disease is an accident; a breach in the economy, which nature is ever intent on repairing. But in this she sometimes fails; and the design of tonics is to supply what is wanting. There is sometimes a deficiency of pure healthy blood; and the preparations of iron restore that fluid to a healthy condition. In other cases, the blood contains an amount of poison; and some tonic must be selected which is capable either of eliminating or decomposing the poison. Mercury probably acts by producing some chemical change in the blood, which renders the poison inert for a time, and, under careful management, for life. But as the salts of iron are liable to create disturbance in the functions, if given in excessive doses, under which circumstances their tonic effects cease, so mercury must be so administered as not to depress the powers of the system, which are required for the destruction of existing disease. So long as the general system does not suffer from the mercurial poison, it will remain capable of taking advantage of the special effects of the mineral as exerted on the morbid condition of the blood. But when the gums become sore, or the bowels disturbed, there is here a new source of irritation and debility. The animal poison may have been in part neutralised; but, if the strength of the system be sacrificed to the action of the mineral poison, it will no longer be able to contend with the original disease, which, although less virulent in its nature, may become more destructive in its effects. It often happens, that syphilitic symptoms will yield under a course of mercury up to a certain point; the disease will then become stationary, and, if the medicine is persevered in, the symptoms will become aggravated. Sores which were healing will again ulcerate, dissipated eruptions will re-appear, and the patient may even fall into a worse condition than before. And yet the disease is as purely syphilitic as ever it was, and as ready to yield to mercury, if rightly administered; but the system being for a time deranged by its excessive administration, the *vis medicatrix naturæ* is paralysed, and the disease is triumphant.

But, apart from theory, the case is practically this. Mercury gene-

rally excites a salutary influence over syphilitic eruptions; but only for a time. It then does harm. Whatever be the reason of this, the practical conclusion is plain. We must then desist; and, if necessary, renew the treatment when the system has recovered from the shock. It is much safer to administer an active remedy, under the guidance of the observable phenomena of its action, which present themselves to our notice, than in obedience to any theory deduced from extraneous sources. That the latter method has been prevalent, both in the excessive, and in the too sparing, use of mercury, is but too apparent.

Every mineral used in medicine has some peculiarity of action, which can only be understood by long and attentive observation; and without a familiarity with these habitudes, we use the medicine at great disadvantage. Too much attention cannot be given to this subject. In order to show its important bearing, the action of mercury may be contrasted with that of arsenic. Thus:

Arsenic	Mercury
Produces its maximum of good by slow degrees, and by continued and prolonged exhibition.	Effects its salutary purposes often suddenly; always within a limited period; or, beyond that period, fails altogether.
Has a cumulative action, the system becoming more and more sensitive to its presence, and intolerant of its influence, in proportion to the quantity swallowed.	Has no cumulative effects after the first few days; and the system becomes less and less sensible of its presence, and more tolerant of its influence, by its habitual use.
May be given until the patient will not bear the five hundredth part of a grain.	May be given until enormous quantities prove absolutely inert.
Affects the nervous system more readily at first, and afterwards the vascular system, the nervous tissues recovering their tone.	Affects the vascular system more readily at first, the nervous system suffering severely after a lengthened course.
Should therefore be added to the blood drop by drop, *cautè et gradatim*, in diminishing doses.	Should be poured in suddenly, until it produces some effect, then as suddenly withheld for a time, and resumed, if necessary, with greater energy.

That the vascular system may be gradually inured to the influence of mercury, so that doses which at first had the power of salivating, may at length be administered without producing any sensible effect; and that, in order to excite as ready an action by a second or third course of mercury, as by the first, the dose must be increased, if not doubled, must be well known to every practitioner. It is also matter of common observation, that the salutary action of mercury on diseased structure, is nearly contemporaneous with the morbid action of the mineral on the gums or other tissues. Accordingly, the common practice has been, not only to make the gums sore, but to keep them sore for days or weeks together, with a view to the continued and protracted effects of the remedy on the disease. As it was once believed that copious ptyalism was necessary to insure the full benefit of the mercurial treatment, so of late it has been generally held, that a continued, though moderate, degree of soreness of the gums is a necessary condition. This opinion appears, however, to rest upon no better foundation than the former now long exploded notion.

Both the one practice and the other appear to be founded on the belief, that the morbid action of the mineral on the healthy tissues, takes precedence of its salutary action on the diseased structure.

Many years' close and anxious observation have established in my mind the opinion, that this is an erroneous view. It is not easy to detect, in an ulcer or an eruption, the first appearances of healthy action; and it is clear that healthy action must exist for some little time before it becomes apparent. If, therefore, the gums first become tender, and the ulcer first presents an improved appearance, on one and the same day, it is fair to presume that the healthy action had been actually set up on the previous day, that is, antecedently to the morbid action on the gums. But further, close observation will generally reveal the fact, that the very appearance of improvement in the diseased parts exists before the gums are in any degree affected. The mercury has effected the good before it has effected the evil. The soreness of the gums, therefore, is a sign, not merely that the mercury has been pushed far enough, but that it has been pushed *farther than was necessary* for the establishment of healthy action in the diseased parts. If a drachm of strong mercurial ointment has been used every night for five successive nights, and if, on the following day, healthy action is substituted for diseased; and if, on the sixth night, the inunction is continued, the gums becoming slightly sore on the following day,—in such a case as this, the mercury has been continued two nights longer than necessary: for the healthy action, which became apparent after the fifth night, must have existed the day before, though unobserved; consequently disease had been actually arrested by the fourth inunction; and the healthy action thus set up, would doubtless have continued, for a time at least, if the mercury had been omitted on the fifth and following nights. The injury inflicted on the gums, therefore, was wholly unnecessary to the immediate restoration of health. The effect has been sudden, and probably instantaneous,—but will it be lasting? Probably not; and the practical question is: Would the effect have been rendered, in any degree, more permanent or satisfactory, by persevering in the mercury? It is now pretty well agreed, that no advantage would have resulted from salivation; for sores which had become healthy at the commencement of a mercurial course, have been but too frequently observed to retrograde under a protracted ptyalism. And the same thing has been observed under a mild but long-continued course, affecting the gums but slightly.

Under the mercurial irritation in any and every degree (whether from the consequent exhaustion of the *vis vitæ*, or from whatsoever cause), the latent virus, if any exists in the system, is liable to break out in an aggravated and destructive form. It is, therefore, not only useless, but in some degree dangerous, to persist in the use of mercury for a single day beyond the date of a visible improvement in the disease. It is, however, often necessary to have recourse to a second course, or even a third or a fourth, in order to effect the final destruction of the disease. Each succeeding course must be more energetic than its predecessor; otherwise little or no effect will be produced. The courses should also be short and distinct, and should be so managed as to arrest disease without disturbing the general health. The case should be watched *day by day*, and an improvement in the disease, ever so slight, be it real and satisfactory, should be regarded as the signal for arresting the course. Then aperients and tonics should be substituted for the mercury; and the very first appearance

of a return of the disease indicates the necessity of a renewed administration of mercury in doses twice as large as the first. By this means disease may often be arrested in an incredibly short time; and when the system is again purged from the mercury, a third course may be administered as a preventive, suspending the mineral as soon as fetor is observable in the breath, or a bitter metallic taste complained of by the patient.

The whole of this practice, which has proved very generally successful, is founded upon the fact, that the action of mercury on the disease is sudden, and of short duration. It is that of a shock; and the impulse appears to be expended upon the organic nerves. In what way such an action on these nerves can permanently destroy a blood disease, it may not be easy to explain:[1] but that the final results are not compromised by the limited duration of the mercurial action is quite certain. Indeed, the radical cure of the disease never proves so difficult as where mercury has been administered in large doses for many consecutive months. The debility thus produced too often renders the system a helpless victim to the disease. Whereas, by short and vigorous courses, the vital powers are roused and invigorated, the appetite is increased, the digestive organs become active, sleep is procured, and the disease appears to yield rather to the *vis medicatrix naturæ* than to any specific anti-syphilitic virtues inherent in the mineral.

These views may appear opposed to the experience of many practical men, who, failing to effect a radical cure of syphilis by a short course of mercury, have seen the disease annihilated at length by a persevering use of the remedy for many weeks together, to the severe injury of the gums. Such cases occurred in large numbers in the early part of my practice; and it was once my opinion, that the benefit was due to the unremitting use of mercury. More recent experience, however, has made it evident, that the disease would have yielded quite as fully to a shorter course, and that the benefit derived from the continuous use of mercury, was all due to the shock produced at the commencement of the course.

A very powerful, yet incidental, illustration of the principles above enumerated, has been furnished by a recent publication from the pen of Mr. Langston Parker. This gentleman has found that by a process of fumigation, the beneficial effects of mercury may be secured with more certainty and less inconvenience than by the usual methods. The advantage is evidently derived from the rapidity of absorption and consequent suddenness of effect. Mr. Parker's practice must, of course, be limited by its attendant inconveniences; but the principle is capable of almost universal appliance. We have had long experience of its value in the use of mercurial inhalation. The fumes of the oxides of mercury received into the fauces have been found to produce the specific effects of the medicine when the system has been proof against inunction. But it is easy to apply the principle to any

[1] The rapidity with which diseased action is exchanged for healthy, under the influence of mercury, reminds one of the chemical changes produced by galvanism. We know little as yet of animal chemistry; but if we look at the action of mercury as electro-magnetic we shall be able to account for many otherwise obscure phenomena.

mode of introducing mercury into the system, which it may be found convenient to adopt.

It will be most needful, however, to be aware of the possibility of severely salivating the patient by an unguarded exhibition of a very few energetic doses. This danger will occur to the mind of every prudent practitioner, and will deter many from adopting the method of treatment above described. But the danger need only be foreseen to be avoided. We must make it our special business, before commencing the therapeutic course of mercury, to administer an experimental course, just to ascertain exactly the degree of mercurial susceptibility inherent in the constitution of the patient. This may be done in the most guarded way; and, if the patient is unusually susceptible, this first trial may prove therapeutical. If not, it will serve to indicate the dose which the patient will bear with impunity.

Neither must it be forgotten, that we now and then meet with a subject wholly and incorrigibly intolerant of mercury; and, even if we can coax the vascular system to bear it, we irritate the nervous tissues beyond endurance. These cases are rare exceptions to a very general rule. Strumous subjects also are apt to bear mercury ill; but by combining the mineral with the preparations of iron, and giving the patient the advantage of the coast, the open air, and a mild season, the difficulty is often overcome, especial caution being requisite lest the gums or glands should suffer irritation. When pulmonary tubercles are discoverable, even in a latent form, mercury is to be avoided. Nothing is so likely to promote their development and maturation as a mercurial course. When syphilis and phthisis co-exist, the case is hopeless.

Much importance is attached by some practitioners to the selection of the medicinal preparations of mercury; some giving the preference to one form or mode of introduction, others to another. Without depreciating the real value of these preferences, it may be questioned whether any general rule can be laid down. Every preparation has its objections as well as its advantages; but both the one and the other are casual, not inherent. The chloride is active and energetic, and invaluable in cases of iritis, where there is no time to be lost; but it is apt to create undue irritation in the bowels. Inunction is a safe and, generally, a sure mode of introduction. But it is a dirty and inconvenient practice; and now and then we meet with cases in which the absorbents of the skin refuse to perform their office: neither can we in any case ascertain how much mercury is actually absorbed. The blue pill is a mild and convenient form for the first course; yet it is liable to remain unchanged and inert in the bowels, or, on the other hand, to be converted into the chloride or bichloride. The latter preparation is often active and useful, but it fails in safe doses to create the salutary shock so necessary to the full effect of mercury on the system. Fumigation, either general or local, presents perhaps more advantages, when it can be conveniently had recourse to, than any other mode,—but it is a difficult and delicate question, how to regulate the dose. It is my usual practice to begin the course with two or three grains of blue pill every night for three nights, by way of experiment. If this produces no effect, an aperient is administered, and after it, five or seven grains of blue pill night and morning, until its salutary

effect becomes visible. In the second course, the dose is increased; in the third, inunction is preferred; in the fourth, inunction, together with frequent doses of calomel, with or without opium. In strumous cases, the bichloride, combined with the compound tincture of cinchona for adults, and the grey powder for children, with some preparation of iron, have been found most useful.

In all cases, regard must be had, not only to the original constitution of the patient, but to his present condition. Both plethora and anæmia are conditions highly unfavourable to the advantageous exhibition of mercury. In the former case, depletion must precede the mercurial course: in the latter, the preparations of iron may be combined with mercury, or otherwise administered.

26, Bedford Square, January 1851.

ON INTERNAL STRANGULATION OF THE INTESTINES.

By HENRY HANCOCK, Esq., Fellow of the Royal College of Surgeons of England: Surgeon to Charing Cross Hospital.

(*Read before the Medical Society of London, January* 4, 1851.)

Cases of Internal Strangulation of the Intestines are so obscure, so difficult of diagnosis, and so fatal; their *post-mortem* examination so frequently develops the probability of relief from early operation, whilst our knowledge upon the subject is so very defective, that great benefit would ensue if all cases occurring in the practice of individuals were recorded, and therefore I am induced to submit the following cases to the attention of the Society; for although they terminated fatally, they may, as collateral evidence, strengthen the hands of the surgeon, and justify him in proceeding to operation earlier than has hitherto obtained.

Case 1. I was, on Sunday the 3rd of November last, requested by my friends, Messrs. Brown of Lewisham, to see the gardener of a gentleman residing at that place. I am indebted to them for the following particulars.

E. P., married, æt. 51, an under-gardener, who had resided in his situation for twenty-three years, about five feet six inches in height, of stout proportions, of active and temperate habits and healthy, except having had inguinal hernia on the right side, for which he had constantly worn a truss for ten years; was on the 17th October, 1850, assisting in raising a tree which had been blown down, and using great exertion, suddenly felt a sharp pain across his abdomen, which almost caused him to faint. He went home, and took some hot brandy and water; the pain subsided in about two hours, and he resumed his usual employment, and thought nothing more of the pain or the circumstance of straining himself. On Wednesday, October 30, thirteen days after the strain, he complained of a slight pain in the stomach, which he attributed to his bowels not having been sufficiently opened for two days, for although on the day previously he had had several evacuations after taking some pills, he felt unrelieved, and complained of pain across the umbilicus. He was ordered eight grains of Dover's powder, with three

grains of calomel, and a strong purgative mixture. On the 31st, the pain in his abdomen was gone, but his bowels had not been acted upon. Calomel grs. iij, scammon. gr. x; to continue the purgative mixture.

Nov. 1. Being considered better, was not seen, but at night sent for more medicine, as his bowels had not been opened. Cal. gr. v, scammon. gr. x, in castor oil, mist. sennæ c. ʒij, 4tis hor.

Nov. 2. Has passed a very bad night and vomited many times. He for the first time mentioned the pain he suffered when replacing the tree, but thought that had nothing to do with his present illness. His abdomen distended, and in great general pain. No tenderness or increase of pain on pressure; no hernia on the right or left side to be seen, felt, or detected; distressing pain about the umbilicus; vomiting almost constant, apparently pure bile; countenance dejected; skin yellow; pulse 126; tongue clean and red; in a profuse perspiration; respiration 21. Introduced a long tube into the rectum and injected about a pint and a half of gruel, with castor oil and salt; it came away immediately with considerable force, and accompanied with a few bits of hardened fæces; two more injections were given at intervals with the same results; to take cal. gr. v, pulv. opii gr. ¼, every two hours, castor oil, with two drops of croton oil, and the compound senna mixture; the bowels to be kept constantly fomented with the poppy fomentation and flannel, and the abdomen to be carefully rubbed. 1 P.M. Remedies continued; vomiting urgent; countenance very distressed; eye sunken; complains of great pain all over the abdomen, but could not make him point out any particular spot; sickness very distressing; skin jaundiced; pulse 130; tongue clean; urine of good colour, passes freely. 5 P.M. Symptoms aggravated; tongue dry; administered another enema, with the same result; ordered brandy and soda-water. 10 P.M. Continues in the same fearful state; has passed a few pieces of hardened fæces, but no wind; the distension of the abdomen has increased, but not the pain.

Nov. 3, 9 A.M. Has passed a most wretched night, until early this morning, when the vomiting ceased for six hours, during which interval he had some sleep; the vomiting, however, returned occasionally. His abdomen much distended, but not in pain; countenance collapsed; thirst great; pulse 136; very feeble; tongue clean; extremities cold; appears sinking fast. 1½ P.M. Continues to get worse. He was seen and examined by Mr. Hancock.

I found the patient in the condition which has been so ably described by Mr. Brown, and after a careful examination could not detect any signs of hernia, either on the right or left side. The patient told me he had worn a truss on the right side for the last ten or fifteen years; but said he was sure the hernia had nothing to do with his present sufferings, as it had not been down, and he experienced no pain in that situation, either during my examination or at other times, whilst he complained greatly of the pain above the umbilicus; indeed he appears to have suffered so little inconvenience from the rupture, that his wife, to whom he had been married twelve months, was not aware of its existence, as she told me that, although she saw the truss, she did not know why he wore it, and that he never complained of anything being the matter with him.

It was evident that the poor fellow was dying, whilst the symptoms and previous history led us to the conclusion that an internal strangulation existed, of some kind or other; but what its precise nature was, whether intussusception, band, or otherwise, or its exact situation, we could not decide with any degree of certainty. However, it was agreed, as presenting the only chance of saving him, that an exploring operation should be performed, and his consent having been freely given, it was proceeded with, with as little delay as possible; but before selecting the spot for operation, a very careful examination of the whole abdomen was made. Not the least external appearance of hernia was to be discovered; the whole abdomen was distended, but not very painful to the touch in any part; but about three inches above Poupart's ligament, on the right side, Mr. Brown directed my attention to a spot at which an elastic and firm feeling was communicated to the finger, and on consultation it was decided to operate at that point. I therefore carried an incision, beginning rather more than an inch above the anterior superior spinous process of the ilium, continuing it towards the linea alba. The abdominal layers were carefully divided in the same direction; and upon coming down to the fascia transversalis, it appeared to bulge at the spot mentioned, and when this was divided, a bulging of the peritoneum the size of a walnut was discovered; this was laid open, and a knuckle of congested intestine disclosed. I sought the seat of stricture, but it was so high up I could not reach it until I drew the intestine gently down for about two inches, when Mr. Brown detained it in that situation, and I was enabled to divide the stricture, which was so firm that we could all distinctly hear its division by the knife. The wound was then brought together, and same brandy and water and opium given to the patient, who, however, died very shortly after the operation.

I was not present at the post-mortem examination, which took place twenty-four hours after death; but I am indebted to Mr. Brown for the following particulars. The intestines contained a considerable quantity of fluid, and were so distended that it was thought necessary to puncture them, and more than three quarts of fluid poured out. The intestines were neither inflamed nor congested, excepting for about four inches, which had been constricted, and which was congested. The constricting band had been completely divided, and no other adhesion or band could be discovered in the course of the intestines, which were perfectly free.

Case II. The next case was that of a gardener to a gentleman residing at Hampstead, to whom I was called by Mr. Willin. He had been wheeling some heavy barrows of turf, and whilst warm drank a pint of ale rather quickly, immediately upon which he was seized with severe cramping pains in the abdomen. He subsequently presented the same symptoms as in the last case. Obstinate constipation, continued vomiting, swelling of the abdomen, and pain referred principally to the umbilicus. The abdomen, though swollen, was not very hard, neither was the pain much increased upon pressure, excepting in one spot over the right iliac fossa. When I saw him, the symptoms were for the time alleviated by calomel and opium; his pulse were better; abdomen softer, and free from pain; countenance

less anxious; and the patient expressed his opinion that he would get well: it was agreed, therefore, to continue the same treatment, unless he became worse, when an operation was to be proposed to him. In accordance with this, on the following day, his symptoms being much aggravated, Mr. Willing suggested an operation, and sent for me to see the patient again; but, in the meantime, he found that the man resolutely refused to submit, whilst the friends locked the garden-gate, and declared they would not admit either of his doctors within the premises. Under these circumstances, nothing could be done; the man lived three days, and then died exhausted. We obtained permission to examine the body, and found the cause of mischief to exist in the right iliac fossa. The appendix vermiformis was turned up, and through the ring thus formed a portion of the ilium had protruded; and I was enabled to withdraw it without the slightest difficulty, as, although the constriction had been sufficient to prevent the passage of the contents of the intestine, it had not been sufficient to produce strangulation, or even inflammation, of which there was no trace.

The anxiety connected with cases of this description is greatly enhanced by the uncertainty attending the exact seat of obstruction, from whatever cause it may ensue; the symptoms are frequently so deceitful, the history so meagre, and unsatisfactory, that we have but little to guide us in the selection of locality. It has been stated that a pretty correct opinion may be formed as to the point of mischief, by the constant pain referred to that spot; but this theory is opposed by the first case related, as here the pain was confined to the umbilicus and pit of the stomach, whilst the patient denied its existence over or near to the actual seat of constriction, over which he could bear considerable pressure without suffering; and, indeed, it was only the particular feeling referred to the touch, upon pretty full pressure, that led us to perform the operation where we did. It might fairly be asked, did not the previous existence of hernia give you some clue to the nature of the mischief, and would not that serve as a guide? It might in some instances; but attention was paid particularly to this point. Not the slightest external swelling or projection at the rings could be detected; whilst the man denied that it had been down, and actually scouted the idea of his sufferings being in any way connected with it: and what still more strongly marks the slight dependence to be placed upon the pre-existence of hernia as a guide is, that I was once present at an operation for the relief of internal strangulation; the patient, a woman, had suffered from femoral rupture of the right side for some years, and it was thought that the then existing symptoms might in some measure be connected with it. However, the evidence was so unsatisfactory, that the surgeon determined upon opening the abdomen at the linea alba; it was then discovered that the hernia had nothing at all to do with the matter, but that the obstruction existed on the other side of the abdomen.

Again, the symptoms are so undecided as often to mislead, or, at all events, to increase doubts as to the nature of the mischief. It is an interesting and important fact, that in these cases the constriction shall be sufficient so to interfere with the functions of the part, as sooner or later to destroy life, without at the same time producing any appreciable degree of inflammation; this was the case in both the

examples here related, and this accounts for the fact that, although in both instances the abdomen was distended, it was not hard; it could bear pressure; and in both the patients could lie with their legs straight down in bed. Again, the first case proves that we have not always the entire and complete arrest of the passage of the fæces to guide us in our diagnosis, as we find the bowels acted more or less for thirteen days from the occurrence of the strain; and I may here observe, that the passage of fæces must not always be looked upon as an unerring sign of complete freedom from constriction, even in strangulated hernia. A woman was brought into Charing Cross Hospital, having had strangulated femoral hernia of the right side, which had been returned after long-continued pressure by a very intelligent practitioner in the neighbourhood; the constitutional symptoms, however, were unrelieved. I saw her the next morning, and determined that should she not be better in the evening, I would perform an exploring operation, as, upon careful examination, the hernia appeared to have been completely returned; upon visiting her at eight o'clock in the evening, for that purpose, I found her improved, and was told that her bowels had been twice moved, and therefore I concluded all would go on satisfactorily; her bowels were again slightly moved on the following day, but, as she complained of some little uneasiness, a dose of castor oil was ordered. She became rapidly wore, and died from general symptoms of peritonitis in the course of a few hours. The post mortem shewed that the hernia, which was very small, had been returned "en masse", but that the sac did not contain the whole calibre of the intestine, but only a portion of its side.

Remarks. Notwithstanding the fatal termination of these cases, I have ventured to bring them before the notice of the Society, in the hope that they may be of service in directing attention to the propriety of interfering surgically at a more early period than what usually obtains, and of abstaining from the indiscriminate employment of purgative medicines, which had better be discontinued when sickness sets in, as they materially increase the patient's sufferings, diminish his strength, and lessen the probability of the operation proving successful. And I would again venture to advert to the fact, that patients in these internal constrictions are frequently destroyed by irritation and impeded function, and not by inflammation; that consequently the symptoms are more negative than positive: positive, for the most part, as regards sickness, constipation, and prostration; but negative as regards the swelling, and character of swelling, of the abdomen; the pain; and condition of the pulse, until at an advanced period. And, indeed, from the various cases which I have seen, but which the limits of this paper will not permit me to enter fully upon, I am inclined to believe that, in cases of constriction within the abdomen, the symptoms are seldom so acute and decided as either in strangulated hernia, enteritis peritonitis, or tuphlo-enteritis.

In conclusion, I would remark that I have here merely intended to submit the account of two cases, with a few remarks; but that I by no means offer this paper to the Society as an essay upon the subject of Internal Strangulation.

59, Harley-street, 31st Jan. 1851.

BIBLIOGRAPHICAL RECORD.

Works enumerated at p. 44.

Introductory Address on Medical Education, with especial reference to the Course of Study required for the Degree of M.D. in the Queen's University, Ireland. By Alexander Fleming, M.D. pp. 32. Dublin : 1850.

In treating the subject of Medical Ethics on a former occasion, we stated our conviction, that all useful reform in our profession must result from the united efforts of its members. We also expressed an opinion, that a great proportion of the evils which afflict us are directly traceable to the want of preliminary education ; which deficiency we regard as the fertile source of those multiform shapes of quackery which produce disunion among ourselves, and make us objects of contempt to the public. We stated, at large, our views as to the amount of general information which ought to be possessed by those who propose to enter upon the study of medicine ; and we intend, on the present occasion, to enter more particularly into the duties which belong to the student, *after he has acquired a due amount of general knowledge*, and when he is fairly launched upon his professional career. We are in hopes that our observations may be not altogether ineffective in awakening the attention of the profession to the improvement of the education of their juniors ; on these latter must the hopes of the profession rest, and by their success, or failure in acquiring sound principles of thought and action, must the future welfare of our common calling be determined.

However much we may have advocated the necessity of classical studies, and other branches of general knowledge in the education of youth destined for the medical profession, we by no means recommend that the student should combine Latin, Greek, and Mathematics, with his purely medical and anatomical studies ; nor do we for one moment defend the present miserable system of a young man wasting his time in superficially learning the Latin grammar at a period when he should be attending to his studies in the hospital or the dissecting-room. We strongly maintain that the former should be mastered *before* the pupil enters upon his strictly medical pursuits. If a boy, who has been under competent tuition from the age of ten to sixteen, has not been able to acquire a competent knowledge of Latin, and of the rules of arithmetic, together with the outlines of history, geography, and logic, he is certainly unfitted for a profession requiring so much mental energy, and such varied acquirements, as the medical ; and if it be ascertained that, from unavoidable circumstances, his education has been neglected up to the period we have mentioned, it would surely be advisable for his friends to put him under tuition for at least another year, before making him enter upon the actual studies of his intended profession. The year, devoted in this manner to preliminary studies, would promote, rather than retard, his real advancement, and might afterwards save considerable trouble, vexation, and expense.

The plans adopted by those who are intended for the medical profession are threefold :—1st. The student is sent to one of the universities, either that of London, Oxford, or Cambridge ; in all these some form of preliminary education is enforced by means of examinations. At Oxford the student must take the degree of Bachelor of Arts ; at Cambridge he must pass the Previous Examination ; at London he must pass the Matriculation, which, as we have stated in other articles, is a comprehensive and efficient test of general literary and scientific acquirements. In all these universities, these examinations must be passed *before* the student commences his medical studies ; but the University of London differs from the other universities in

not requiring residence for its degrees, and also in allowing the examinations to be passed at an earlier age than is permitted at the other seats of learning. This plan is adopted by those who aspire to the highest ranks of the profession.

2nd. The student is placed for two or three years with a practitioner, to learn the rudiments of his profession, before beginning to attend lectures and hospital practice. This system is called apprenticeship, from the French word *apprendre*, to learn; and, in the indenture, the master enters into a covenant to instruct his pupil, *or to cause him to be instructed.* We need hardly inform our readers that, although by the Act of Parliament it is required that the apprentice should remain with his instructor *five years*, it is practically necessary that he should serve only two; and, indeed, he need not actually serve him at all; for if his master is unable, or unwilling to instruct him, and allows him to obtain his information from other sources, both the letter and the spirit of the Act are maintained. This second plan is very generally adopted by those who are to become general or family practitioners.

3rd. The pupil is sent, at the age of eighteen or nineteen, with little or no preliminary education at all, to one of the great cities of London, Edinburgh, or Glasgow; he is placed under no control, is subjected to no previous examination, and is left pretty much to follow his own inclinations as to the method of pursuing his studies. This system qualifies a pupil to present himself as a candidate for the diploma of the Royal College of Surgeons of England, or for the degree of Doctor of Medicine at one of the Scotch universities. We are very far from asserting that all those who belong to any of those learned bodies are destitute of a knowledge of general literature and science, but it is a notorious fact, that no *evidence* of preliminary knowledge is *required* at any of these institutions. We should also qualify our statement by admitting, that the English College of Surgeons requires an extensive array of general knowledge from its *Fellows;* but as these form, and are likely for a long time to form, only a very small fraction of the profession, our remarks are not practically invalidated.

Of these different methods of professional education, the first is incomparably the best; though it must be granted, that the two latter have been followed, in early life, by some of our most eminent practical physicians. The evidence of preliminary knowledge, which the student is required to give, insures a certain amount of previous mental training, and proves his capability of grasping the difficult subjects which will afterwards be presented to his attention; while the progress of his subsequent studies is ascertained, at different intervals, by oral and written examinations. Those who pass successfully through these ordeals are justly entitled to take a leading position in the medical profession.

The second plan, which is less laborious and less expensive than the first. is very well adapted to those whose means are limited, and whose time of study is brief. Supposing the master to be a man of average honesty, and the pupil a youth of average intellect, the period of two years is spent not unprofitably in acquiring a general knowledge of the profession; but, supposing the master to be a man of intellect as well as honesty (and we know there are many such), the period so passed is valuable in the very highest degree. We need hardly state, that the idea of representing apprentices in the light of menials is merely a poetical fiction, which might have been applicable during the last century, when Parson Trulliber was regarded as a humorous sketch of some of the peculiarities of the English clergy, and when Captain Oakum and Dr. MacShane were admitted as portraits of certain characters who then figured in the British navy. We do not desire that the legislature should retain the system of apprenticeship; but we are quite confident that if it were abolished immediately, a plan of a very similar character would be voluntarily adopted in a vast number of cases.

The third plan is undoubtedly the worst that was every tolerated by authority, and is in our opinion wholly inconsistent with that discipline of

the mind which is absolutely necessary in learning a profession. Admitting, as we cheerfully do, that many young men who have been sent to study at one of our great metropolitan cities, have at once entered into a severe course of mental and moral training, and have eventually become ornaments of the profession; yet it is notorious, that multitudes of young men so situated, fall into idle and dissipated habits, and at the end of their academical or hospital career, manage to squeeze through their examination by the help of a grinder, or what is just as common, abandon the profession altogether in disgust. We cannot understand why the candidate for holy orders should reside for a certain time at college; why the embryo barrister should keep terms in one of the inns of court; why the future attorney should be articled to a senior in the same profession; why the junior officer in the army, or navy, should be for a period placed under the control of superior authority; and why the junior member of the medical profession alone should be exempted from all superintendence.

We do not hesitate, therefore, to express our decided opinion, that, putting the system of apprenticeship entirely out of the question, it is clearly to the advantage of the junior members of the profession that something of a collegiate course of education should be most strongly advocated; for, admitting that this system may not in all cases reform the vicious, or sober the thoughtless, yet it cannot be denied that such a system is more likely to be advantageous to the student than that which throws him at once upon his own resources in one of our great cities, without a friend to cheer his loneliness, and without a guide to direct his steps.

We conceive that all these circumstances have a most important bearing upon Medical Ethics; for as the child is father to the man, so must the student be the parent of the practitioner. We are not disposed to argue with any severity upon the follies of youth, and we are disposed to make many allowances for the exuberance of spirits which characterises the springtime of human existence; but it cannot be questioned, that it is the duty of the senior members of our profession, whether teachers, writers, or practitioners, to direct the dawning energies of the youthful mind in a proper course, and to impress upon the understanding the conviction of the importance of the mission which the medical practitioner is called upon to fulfil. Nor can it be denied that habits acquired in early life have a most important influence upon a man's future career; and hence we have urged, and shall continue to urge, most emphatically, the necessity of establishing habits of order and discipline at the earliest possible period. It is for this reason, that, in the absence of a collegiate system, we have refrained from joining some of our contemporaries in their denunciations of apprenticeships; for even supposing the practitioner, who takes an apprentice, to be a man without striking ability, yet, if he be a person of good moral character and respectability, the arrangements of his house will involve, on the part of the pupil, an attention to those minor duties and decencies of life, which, although apparently unimportant, have a very considerable influence in forming the character, and elevating the moral feelings. Under any system of medical education, a pupilage of two or three years with a practitioner would always be recommended, as a preliminary, or as an accompaniment to medical studies; and, indeed, the system of private superintendence has certain advantages over the collegiate plan; for, in the latter case, there is an uniformity of expense, which is inapplicable to all cases; while, in the former, the pecuniary arrangements may be made according to the means of the respective parties. It is also obvious, that a pupil who is placed in immediate personal contact with a practitioner must have numerous opportunities of acquiring a practical knowledge of many parts of the profession; and even if he be compelled to work at practical pharmacy for some time, we consider that it is advantageous rather than otherwise. We do not advocate the propriety of devoting *five years* to such a purpose; but we do not argue against

such a waste of time, simply because it is neither required by law, nor now sanctioned by custom.

We cannot help expressing our deep regret that some uniform plan is not adopted in all British universities and medical schools, for obtaining some evidence of preliminary knowledge from the pupils on commencing their medical studies. At the English universities we have seen that the student must pass an examination in arts; but in Scotland no such test is required; and hence it has often happened that students have entered upon, and have completed their medical career, without possessing even an elementary knowledge of the classical languages! We find, by referring to the Minutes of Evidence upon Medical Education, taken at a Committee of the House of Commons, that a considerable number of Scotch graduates have been rejected at the Apothecaries' Hall, in London, from their inability to translate prescriptions!! This lamentable result may be fully explained by the laxity of the system formerly pursued at some of the Scotch universities, where students were received indiscriminately, without any inquiry being made as to their previous education. While thus unequivocally condemning the practice of allowing students to complete their medical career without any reference to their attainments in general science, we are happy to notice, in terms of commendation, the following Regulation of the Royal College of Surgeons of Edinburgh, and we only regret that the amount of preliminary knowledge required should be so small. "Every candidate for the diploma of the Royal College must, either previously to, or during his medical education, have received regular instruction in the elements of mathematics; and must have subsequently attended a course of mechanical philosophy, of at least three months' duration, and of not fewer than sixty lectures." It is a pity that the student is not *examined*. Evidence that he has paid the money for lectures is not sufficient.

In Ireland, it appears that the constituted authorities are sensible of the importance to be attached to general science, as a preliminary to medical education. Trinity College, Dublin, requires that the candidates for the degree of Bachelor of Medicine shall have previously taken the degree of Bachelor of Arts, or shall have, at least, completed the usual education and examinations in arts of the first two years of the undergraduate course. The Royal College of Surgeons of Ireland requires that the candidate for examination should produce a certificate that he has passed a previous examination as to his acquaintance with the Greek and Latin languages. The Apothecaries' Hall of Ireland requires that every candidate shall be examined, *before his apprenticeship*, in the following books: the Works of Sallust; the first six books of the Æneid of Virgil; the Satires and Epistles of Horace; the Greek Testament; the Dialogues of Lucian; the first four books of Homer's Iliad; the first six books of Telemachus, the History of Charles the Twelfth (in French); the first two books of Euclid; and algebra.

The little work, of which the title stands at the head of the present article, is a very able address to the medical students of Queen's College, Cork, and we may state that the views advanced by the lecturer are quite in accordance with our own. We find, that in order to graduate in the Queen's University in Ireland, it is necessary that the student should pass a matriculation examination, and that he is recommended, though not compelled, to graduate in arts. Dr. Fleming, taking the same views as those which we have repeatedly advanced, argues very strongly in favour of preliminary education, in order to place the practitioner of medicine at least upon a level with the members of the other learned professions. He recommends the student to make himself acquainted with the classical languages before the commencement of his medical studies, and he very properly recommends, in addition, an acquaintance with the French and German languages. "Thus educated," says Dr. Fleming, "with his mind invigorated and stored with a large amount of general and useful knowledge, the student is prepared to enter with advantage

on the special and more complex studies of his profession, and he may aspire, not merely to the successful practice of a routine art, but to the complete knowledge and advancement of a most difficult science. *Your preliminary knowledge already tested by examination*, and your medical studies once begun, I recommend you to give your almost undivided attention to the latter. The earnest student is quickly enamoured of his studies, and, conscious of their extent and immense importance to his future career, is most unwilling to devote time to any pursuit not having a direct and obvious bearing upon his profession." Here we must pause for the present.

(To be continued.)

Remarks on Insanity: its Nature and Treatment. By Henry Monro, M.B. Oxon., F.R.C.P. 8vo. pp. 150.

Dr. Monro's object, in this very interesting essay, is to prove that insanity is a disease of a corporeal nature; that, without seeking for any more subtle or metaphysical cause, we may believe insane phenomena to arise from those states of *irritability* and *deficiency* of action in the sensorium which are the consequences of loss of nervous tone. That this loss of nervous tone is caused by a premature and abnormal exhaustibility of the vital powers of the sensorium; that this infirmity is essentially a local one, though torpor of the general physical and vital powers assists it; and that its origin is to be esteemed constitutional, congenital, and frequently hereditary.

"As a part of, and arising from this theory, the *coincident excesses* and *deficiencies* of mental phenomena, manifested by the insane, are attributed to the *coincident* existence (in different parts of the sensorium) of those two stages of loss of nervous tone; *irritable excess of action* and *paralysis*. This view of the case renders it unnecessary to believe that the violent excesses of the insane must arise from a too sthenic condition of the system; a doctrine which experience so much contradicts, but which the want of experience so often propagated."

These views are supported by a comparison of the history of insanity with the history of other imperfect conditions of the mind; as dreaming, somnambulism, voluntary abstraction of mind, passion, the mind of infancy, senile imbecility, intoxication, fever, etc.

They are then illustrated by an examination of the actual physical condition of the insane, including a discussion of the relation which the condition of the vascular system holds towards the disease. This is considered under the three heads of inflammatory action, deterioration of blood, and pressure. The depressed state of the general vital and physical powers of the insane are then reviewed; the existence of keenness of sensibilities is shown to be a frequent concomitant of such condition; and the proneness of the female sex to insanity is adduced as corroborative of the theory.

The whole concludes with the narrative of cases successfully treated in accordance with these views.

We cordially recommend this little work to our readers, as being the production of one fully and practically acquainted with the subject. At the same time we must record our conviction, that inquiries must be pushed still further before we arrive at the ultimate step. The *cause* of Dr. Monro's cause must be looked for and found, before we can ascertain correctly why loss of nervous tone produces these special phenomena, seeing that in numberless instances there exist nervous defects without one symptom of mental disease.

The Philosophy of Vital Motion. By Charles Bland Radcliffe, M.B. pp. 158. London: 1851.

This author, who has written a very good work entitled *Proteus, or the Law of Nature*, which was reviewed last year in this Journal, now comes

before the public with a philosophical work on physiology. As in his former work, Dr. Radcliffe exhibited considerable ability in bringing a great store of botanical and zoological knowledge to bear in his treatise on the *forms* of organic bodies, so, in the present work, he employs his resources in illustrating the nature of the *motions* which they perform.

He traces first the motion of fluids in the cells, and vessels, and intercellular passages of plants; then he treats of the motion of fluids in the lowest tribes of animals. Ascending in the scale of creation, he then describes the movements observed in the muscular coat of the alimentary canal, and involuntary muscles; and, lastly, he describes the vital motions of the heart, and the circumstances which influence its functions.

Although there is no originality in this little work, it is very well put together, and exhibits considerable powers of research and of condensation; and although we do not like it quite so well as the author's former publication, we consider it nevertheless a very creditable production.

Die Geburtshilfliche Praxis, erlaeutert durch Ergebnisse der II Gebarklinik zu Wien, und deren stete Vergleichung mit den statistischen Ausweisen der Anstalten zu Paris, Dublin, etc. Von Dr. F. H. Arneth, Assistent an der II Gebärklinik zu Wien. pp. 254. Wien: 1851.

[The Practice of the Second Obstetric Clinic at Vienna, compared with that of the Lying-in Institutions in Paris, Dublin, etc. By Dr. F. H. Arneth.]

This work consists of a statistical analysis of the cases admitted into the second division of the Lying-in Hospital at Vienna, from Oct. 15, 1847, to the same day in 1849. Prefixed is an account of the general management of the institution, together with a table, shewing the annual results from the time when it was built by the Emperor Joseph the Second, in 1774, to the end of 1849. The total numbers are; females admitted, 204,243; children born, 189,185; deaths of mothers, 7878, or 3·85 per cent.; of children, 11,092, or 5·86 per cent. In that part of the hospital which Dr. Arneth more particularly notices, the results, since it was opened in 1833, have been the following: children born alive,—males, 19,434, females, 18,573; born dead,—males, 859, females, 706; twin births, 442; triplets, 3; females admitted, 39,121; deaths of mothers, 1,583, of male children, 890, of female children, 621.

During the period included in Dr. Arneth's report, there were 6,527 women delivered; 3,280 male chileren, and 3104 females, were born alive; 118 males, and 106 females, were still-born; there were 88 cases of twins; 127 of the women, and 129 male and 115 female children, died. The statistics of the various complications occurring in obstetric practice are given, and illustrated by concisely reported cases. A very valuable feature of this work is, that the author has collected the statistics furnished by Mesdames Lachapelle and Boivin, of Paris, Drs. Boer, Klein, and Bartsch, of Vienna, and Drs. Collins, Mc Clintock, and Hardy of Dublin, Dr. Simpson, Dr. Oldham, etc., and has, partly in the text, and partly in tables, placed them in juxtaposition with the results of his own observations.

Puerperal convulsions occurred in 13 cases. Their more frequent occurrence in primiparæ is noticed by the author, who states that 8 cases out of 13 occurred under this condition. Of the 13 cases, was one of twins; one of delivery at the sixth month, and one at the seventh month. Ten of the children were males. The ages of the patients ranged from nineteen to twenty-eight years. The author adverts to the fact, that in nearly all the cases, observed by himself and others, the head of the child has been the presenting part.

Great credit is due to Dr. Arneth for his pamphlet; which we regard as a valuable contribution to the statistics of midwifery.

CRITICAL DIGEST OF THE BRITISH AND FOREIGN MEDICAL JOURNALS.

ANATOMY AND PHYSIOLOGY.

CASEIN IN THE BLOOD; SYNTHETICAL PROOF BY FORMATION OF ARTIFICIAL MILK.

Dr. Panum, of Copenhagen, of whose interesting accounts of the discovery of Casein in the Blood, we gave a translation in the July number of this Journal for 1850, has published two additional articles on the subject in the *Bibliothek for Læger* for April and July 1850.

In his article in the April number, after recapitulating the facts brought forward in his previous paper, and pointing out the difficulty of establishing a chemical or a physiological distinction between casein and coagulated albumen, the author observes :

" If we institute a comparison between the substance precipitated from blood-serum by means of water and diluted acetic acid, and albumen separated in the same manner from its combination with soda, *we find* truly greater differences than can be distinguished between casein and coagulated albumen. . . . . .

" Before the publication of my former contribution, I had already performed various experiments with the view of instituting a more accurate comparison between the material under consideration and albumen separated from its combination with soda. To procure albuminate of soda, I separated the albumen from the serum, then added soda, and applied slight warmth. A greater or less quantity of albumen (according to the quantity of soda employed) entered into combination with the alkali as albuminate of soda, and was precipitated by acetic acid. A difference was here observed between the albumen of serum and that of an egg. For while albumen from an egg required no warming to promote its entering into combination with soda, or its precipitation by means of acetic acid, the albumen of serum had to be slightly warmed before it would unite with an alkali, or give a precipitate with acetic acid.

" The albumen which was precipitated from albuminate of soda, as above described, was always *soluble with difficulty, even in a considerable excess of acetic acid ;* eight or ten parts of acetic acid to one of albumen produced no solution. On the other hand, the material *originally* present in the serum, and precipitated from it by acetic acid, was soluble in so slight an excess of acetic acid, that it is almost a *finer test of the acid, alkaline, or neutral properties of the liquid, than litmus paper.* This difference seems important ; and can scarcely be without essential influence on the organic economy . . . .

" The precipitate thrown down by acetic acid from albuminate of soda, appears as *firm flocks,* which are not changed by shaking, and which resemble what is seen when a not too highly diluted solution of albumen is boiled. The other matter produces a perfectly homogeneous opacity in the liquid, and only after some time forms something like a solid deposit in the bottom of the vessel, which, however, immediately disappears, and is resolved into a general opacity, when the liquid is slightly moved.

" Moreover, if the albumen precipitated from a somewhat diluted solution by boiling, or from a solution of albuminate of soda by acetic acid, be collected in a filter, it forms, when half dry, *an elastic mass, by no means glutinous.* The other substance, on the contrary, when half dry, forms *a very glutinous mass,* almost like turpentine or bird-lime.

" The albumen, when collected in a filter, has, when dry, a *dirty yellow-*

brown colour. In my previous contribution, I referred to the circumstance, that the substance I am describing sometimes assumed a *beautiful green colour* when thoroughly dried. At that time, I attributed it more to accidental circumstances than to any essential difference, that the substance became green or yellow-brown on drying, as from the same serum I sometimes procured a green and sometimes a yellow product. I now find, that the substance is always of a beautiful green colour when the serum is perfectly clean and free from red blood-corpuscles. But if serum be used, in which there is found a greater or less number of blood-corpuscles, the green colour is effaced by the accompanying redness of the blood, and the product becomes either dirty yellow or dirty brown, according to the number of blood-corpuscles. The green colour is removed neither by alcohol, ether, nor water, and seems to belong essentially to the casein.

"However lightly these differences may be thought of, they are yet not less important than the distinction already referred to, between the so-called soluble casein and albuminate of soda. The preconceived opinion that the material under consideration must be albuminate of soda can thus no longer serve as a proof against its identity with what is called casein, or the essential nitrogenous constituent of milk."

Relative quantity in the blood. Dr. Panum states that he is engaged in a quantitative analysis of the casein in different individuals. He does not yet attempt to draw conclusions; but states that in 1000 parts of dried serum he has found in men, in 3 cases, from 4 to 7 parts; in 8 cases of women, from 5·5 to 12·5 parts. The greatest quantities (9·9—11·4—12·5) were in lying-in women shortly after parturition. In nurses there was an average of from 6·5 to 7·4 parts.

Formation of artificial milk. In the July number of the *Bibliothek for Læger*, Dr. Panum writes as follows:—"It occurred to me that the question of the identity of the material I have been describing with casein, might be solved by the *synthetical* method, which, though it can seldom be satisfactorily employed in scientific diagnosis, yet in the inability of analytical chemistry with regard to the protein compounds, is not to be despised. If it were possible, by adding the necessary constituents, to form from the substance under consideration some universally known product containing casein, such as milk or cheese, we should have a striking proof of the identity of the substance with casein.

"I obtained a quantity of serum from bullock's blood. To this I added acetic acid, in the proportion of six drops of concentrated acid to an ounce of serum, and then a considerable quantity of water. The substance described in my former contributions sank on standing to the bottom of the vessel, so that the superabundant clear fluid could be poured off. On again adding water and letting the substance sink to the bottom, it was rendered almost perfectly free from soluble albumen, etc. After it had settled as much as possible, the water was poured off, so as not to waste the substance, which remained suspended in a greater quantity of water than casein is diluted with in milk. It was now my object to find out, whether the solution of this substance produced by salts or an alkali could be brought to coagulate by contact with the mucous membrane of the stomach of kittens or puppies; and whether it were possible to produce a substance which, in taste and other circumstances, should agree with milk. But as it would probably be difficult to make animals use the solution as milk, unless the other constituents of milk, namely butter and sugar, were mixed with it, and as the taste and peculiarities of cheese might be modified by them, I first tried, by adding these substances, to produce a liquid which should have some resemblance to milk. At a temperature of 30 Raumur, I added to the milky liquid phosphate of soda, till all the supposed casein was dissolved. I then added butter and sugar in the proportions in which they are usually

contained in milk, and, after the butter was melted, I shook the whole mixture in a flask. The liquid, at first greyish or dirty yellow, became of the colour of egg-flip, and, as it cooled, became more and more like milk. The clearer and the less mixed with red blood-corpuscles the serum was, the clearer was the solution and the whiter the milk-like fluid. If the serum was perfectly free from blood-corpuscles, the emulsion, when diluted with water, had the same bluish colour as milk and water; but if there was a strong blood-red tinge in the serum, the solution in phosphate of soda had a reddish and the emulsion a weak yellowish tint. The product had a taste which bore a most striking resemblance to that of true milk; only it was a little more sweet, and left a feeble, though recognisable, bitter after-taste.

Under the microscope, I observed in the emulsion innumerable small globules, exactly like those in milk. On comparing them with those found in milk, scarcely any difference could be perceived, except that their average size in the artificial milk was somewhat greater than in the natural. The globules in the artificial milk were surrounded by a covering, and not simple drops of oil; this covering often showed a distinct though very fine folding, especially on the larger globules. The globules (like those of true milk) were not dissolved in ether, until the covering had been removed by treating them with nitric acid. But by the side of these small globules there were some which were somewhat greater, and presented in their interior appearances which, if they had been furnished from the organised body, would have been certainly considered as nuclei, granular cell-contents, etc. . . .

As the difficulties, which might have been expected to arise in the microscopic comparison of the artificial and the true milk, had so unexpectedly disappeared, I felt myself called on to inquire whether any more perfect imitation could be attained. The most striking difference, which the artificial milk presented on a superficial examination, was that it required a far shorter time than real milk to form a layer of cream on the surface, and that, after standing some time longer, a layer of clear liquid was formed at the bottom of the vessel. I ascribed this failure to the greater average size of the globules in the emulsion, as compared with true milk-globules. When I employed sugar of milk in place of common sugar, the emulsion was uniform, and shewed no layer of clear liquid at the bottom of the vessel, even when more water was added. At the same time, the average size of the corpuscles became less, so that they could not be distinguished by their size from the true milk-globules, and they were now free from any appearance of nuclei or granular cell-contents. The cream was longer in rising to the surface; and the great sweetness which the emulsion had, when made with common sugar, was no longer prominent, so that the liquid tasted still more like milk. A slight smack of salt disappeared, when the butter was washed in water; and a slightly harsh taste of the butter was still farther removed when unsalted butter was used, which had been freshly churned, and washed with water. There was still a slightly bitter after-taste, but this was removed by using carbonate instead of phosphate of soda; a much smaller quantity of the former salt being required to produce the required solution. It was now impossible for me to recognise, by the taste, any difference between artificial and real milk. As, however, it might be said that "*de gustibus non est disputandum*," I submitted the liquid to the taste of others, with the same result. . . .

It now only remained, to render the agreement perfect between the artificial and true milk, that the former should coagulate when brought into contact with the mucous membrane of the stomach. When I used common sugar, it was not wonderful that my attempts thus to make the liquid coagulate, failed; for it is well known, that the addition of sugar to milk retards or prevents its coagulation. But, even after I had used sugar of milk, I could not perfectly succeed in making the milk coagulate. Instead of fresh calf's stomach I used the artificially prepared swine's stomach, which

is commonly used in the dairies, with or without a temperature of 40 R.; and I also gave the liquid to two kittens, who drank it greedily, and whom I then killed. Under these circumstances, as well as by mere standing, the artificial milk turned, and separated into a clear liquid, and a thick curdy mass, which had very strongly the well known smell of sour milk; but I could not produce a consistent coagulum, which could be collected in linen, and pressed out. But when the original substance separated from the serum, after being washed from soluble albumen, was warmed, it formed masses resembling pressed curds, and could be collected on a cloth, while the liquid ran through quite clear.

The identity of artificial with natural milk, and of the substance found in the blood with casein, may seem to be not proved; yet the resemblance is so great as to strengthen the probability of their being identical. I have in vain endeavoured to produce from albumen, precipitated from albuminate of soda by acetic acid, and dissolved in phosphate or carbonate of soda, a liquid having the slightest resemblance in taste to milk.

WYMAN ON THE ARRANGEMENT OF CANCELLI IN BONE.

Professor Jeffries Wyman has stated these general conclusions as to the arrangement of the cancelli in human bones.

1. The cancelli of such bones as assist in supporting the weight of the body, are arranged either in the direction of that weight, or in such a manner as to support and brace those cancelli which are in that direction. In a mechanical point of view, they may be regarded in nearly all these bones as a series of "studs" and "braces".

2. The direction of these fibres in some of the bones of the human skeleton is characteristic, and, it is believed, has a definite relation to the erect position, which is naturally assumed by man alone.

These structures are most uniform and clearly defined in adult and middle-aged skeletons.

In the lumbar vertebræ, which support the weight of the body vertically, these cancelli run vertically and transversely, the vertical fibres directly sustaining the pressure, the transverse ones bracing them at right angles.

The neck of the thigh-bone is adapted to resist pressure by its oval form, the longest axis being vertical, and by the greater thickness of the wall of bone on its under side, to which the weight is more directly transmitted. Dr. Wyman describes another provision, which consists "in having the cancelli of each femur so arranged as to form a segment of a framed arch or truss, which co-operates with the external shell in sustaining the weight of the body; the necks of the two femora forming together opposite segments of an arch". He describes two sets of cancelli. One set rests or abuts on the convex surface of the thick shell which forms the under wall of the neck, and from this they diverge toward the upper portion of the head, neck, trochanter major, and portion of the shaft just below this last; those which extend into the head are much the longest. The fibres of the second series are arranged in parallel curves, the extremes of which are attached on the one hand to the wall of bone at the base of the great trochanter, and on the other to that portion of the preceding class of fibres which supports the upper surface of the head, as well as to the shell of bone between it and the trochanter. Both of these series are braced by other fibres, which are arranged at right angles to their direction. The cancelli of the great trochanter have no determinate form. The internal fibres thus act as braces, assisting the outer walls to support the weight of the body; the curved fibres resisting by their tenacity, the straight or radiating ones by their rigidity. The long straight fibres transmit weight directly to the under side of the neck, and are themselves supported by the curved fibres, and these in turn by the radiating fibres.

In the lower part of the femur and the tibia, the cancelli are adapted to support vertical pressure.

On the astragalus, the pressure is vertical; but this bone rests on two others; one below it, the os calcis, the other in front, the scaphoides; within there exist two series of cancelli, directing the pressure on the surfaces of support. Very nearly the same description applies to the os calcis, where there are two intersecting sets of fibres, the one radiating, the other in concentric curves.

These peculiar arrangements are not found in quadrupeds, and only traces of them exist in the apes, which most resemble man. In him, they are mainly or entirely confined to bones directly connected with locomotion. A certain direction of fibres in each instance coincides with a certain direction, or certain directions of the transmission of pressure. From this constant association of structure and function, says Professor Wyman, the inference seems unavoidable, that they are means and ends. [*Boston Journal of Natural History*, vol. vi, No. 1, p. 125, as quoted in *Trans. of Amer. Med. Assoc.*, vol. iii, p. 53.]

PRACTICE OF MEDICINE AND PATHOLOGY.

THE IMPORTANCE OF CERTAIN PREMONITORY SYMPTOMS OF SEVERE CEREBRAL DISEASE.

The following is a slightly abridged translation of an instructive memoir published by Dr. Devay, of Lyons, in the *Gazette Médicale de Paris* for January 4th and 11th, 1851.

Those severe cerebral affections which rapidly terminate existence, and still more those which, before the fatal issue, gradually destroy the intellect, sensation, and motion, have been the object of much research. Notwithstanding numerous physiological experiments, vivisections, autopsies, minute examinations of the different degrees of consistence and colour of cerebral substance, etc., the knowledge of the physician has been but little enriched. The cranial vault offers an inflexible resistance to exploration; and this should impress on us the necessity of depending less on anatomy in the study of cerebral diseases. Instead of studying the brain when it is dead or dying, we should fix our attention on the unusual manifestations, and carefully collect the various aberrations, either of sensibility or of motion. If we cannot examine the brain by palpation like other viscera, if we cannot auscultate it, as we do the heart or lungs, and thus seize on, by means of one or more of our senses, its successive degradations, we can, at least, detect its commencing affections, by observing the derangements of the functions over which it presides—the intellect, sensation, and motion.

Researches of this kind embrace the premonitory symptoms of diseases varying in their anatomical relations; they take a view of all those affections which arise from an alteration in the brain, properly so called, from apoplexy to mental alienation. But even when, in a given case of cerebral disease, the elements are most favourable, a diagnosis can only be formed with reserve. Thus, when we expect to find softening, we may meet with induration of the cerebral substance; we may expect to find tubercles, and discover hydatids, or osseous tumours. The phenomena presented by patients have not then always that conformity, which would permit particular symptoms to be accurately referred to certain determinate forms of pathological affections. This clinical difficulty in the appreciation of the symptoms of confirmed disease, exists in an equal degree with regard to the interpretation of the premonitory symptoms. These may point to a functional derangement of the encephalon, without any anatomical lesion; and, when the latter is present, it may vary in its form. The infinite variety of forms,

presented by the symptoms of a cerebral disease, can no more be explained by the various conditions in which the organ is found, which has been their seat, than the different modes, in which the same function is performed in different individuals, can be accounted for by anatomical differences in the part which is its instrument. Nevertheless, the study of premonitory symptoms may be useful, even for the anatomical diagnosis of the affection.

After having devoted a considerable number of years to the attentive observation of the severe affections of the brain, we have become convinced, that there *most frequently* exists, especially in those which have a chronic course, a precursory stage, the signs in which are the diminutives of those symptoms which will, at a later period, constitute the more advanced degree of the disease. Thus, slight want of power in the lower limbs, and defect of precision in certain movements, represent paraplegia, or complete paralysis; and a slight alteration of the intellect bears the same relation to the delirium following it. In certain cases, without doubt, a sudden effusion of blood, breaking down the cerebral structure, may suddenly cut off an individual who a few moments before seemed in perfect health; in this case we admit that there has been no intermediate stage—that the index to the explosion has not existed. But this is by no means the case in a very great number of other forms of apoplexy, in which, as may be easily proved by examples, the precursory symptoms, denoting cerebral lesion, may continue for a long time. These forms of cerebral hæmorrhage enter then into the category of those severe affections of the brain—softening, induration, mental alienation, etc. —where a hidden molecular change has been going on before they have declared themselves. Andral, in speaking of certain premonitory symptoms of cerebral hæmorrhage, says: "Their existence incontestably proves that, before the blood is effused, there is already a morbid action going on in the brain, the nature of which it would be important to determine."

I. Premonitory Signs, furnished by the Intellectual and Moral Faculties. Almost all authors of repute have mentioned, without always attaching much importance to them, the disturbances of intellect which precede attacks of severe cerebral ideas. M. Gendrin says: "Apoplectic attacks are often preceded by a difficulty in undertaking intellectual work, by an incapacity for unusual attention, by an extraordinary irascibility, by a morose weakness which exaggerates impressions, and produces terrors without a cause, or by unreasonable anxiety concerning ourselves, or those related to us."[1] Insanity also has its period of incubation, its premonitory symptoms; and frequently it is found that the first act of insanity, which caused alarm, has been preceded by several symptoms which had escaped observation, and sometimes the first phenomenon of the disease has been taken for its cause. The insane often combat their false ideas, before the disorder of their reason, and the internal contest which precedes the explosion of their madness, are perceived.[2] The most general precursor of every severe affection of the brain is a state of *cerebral lassitude*, presenting much analogy to that state of intellectual torpor which follows severe or pestilential fevers. There is observed in the habitual gesture of the patients, in their attitudes and movements, a total absence of what may be called the consciousness of action. The brain seems to have lost its *balancing* power over the *ensemble* of the functions of the life of relation. These patients are often in a constant state of slight habitual vertigo, which they call *weakness of the head*, and which is frequently accompanied by debility in the limbs.

The *memory* is frequently impaired in the precursory period of cerebral affections. Thus, patients have forgotten the names of their friends, or of the most common things. In conversation, they have difficulty in finding

[1] Gendrin. Traité philosophique de Médecine pratique, tome i, p. 487.
[2] Esquirol. Des Maladies Mentales, tome i, pp. 77 et suivant.

the proper word to express their meaning, and are obliged to make use of circumlocutions. More rarely, the memory becomes more powerful; it seems to take a new flight, and reproduces, to the great astonishment of the patient and his attendants, events which had seemed to be entirely forgotten. The curious and inexplicable fact *of reminiscence* corresponds to the exaltation of the special sensibility of certain senses. It is sometimes observed after a slight attack of apoplexy. Professor Brachet has communicated the case of a man, aged 50, who was attacked with apoplexy: he preserved his speech, but could only express himself correctly in the *patois* of his country, which he had entirely forgotten while in health.

Next to the impairment of the memory, and also of the attention, which is fixed with difficulty, or not at all, on objects presented to the notice of the individual, the most striking change is in *volition*, which is diminished. The man who has hitherto been most firm, who has shewn most tenacity in his views, who has pursued the plan of his life with great determination, becomes, in a measure, like the toy of a child; those who are about him, even his inferiors, can command him. Human depravity has often taken advantage of this moral decadence for culpable ends; and the man who has hitherto most rigorously and carefully managed his affairs, is all at once spoiled of his goods, either by extorted donations, or by burdensome expenses. The public see in these cases *bizarreries* of character; the physiologist and the physician see in them the first expression of a pathological condition. This weakening of the will, which, according to our observations, is chiefly connected with those cerebral lesions which lead to lunacy, or to paralysis of the insane, necessitates an alteration of the judgment. . . . . The will is the result of the other faculties; and it is not because it is wanting in the idiot, or lunatic, that they are irresponsible; but rather because they are ignorant of the rules which should direct it.

There is but a slight transition from this to *perversion of the moral faculties*—one of the most mysterious points in psychology. It would seem as if the balancing power of the brain, which regulates the locomotive movements, were also defective as regarded the moral part of the man, so that he fell under the empire of instinct. Hence arises degradation of ideas, and lascivious conversation, in persons who have hitherto appeared full of decency and modesty. And this vitiation of the moral faculty may break through the sphere of theory, and become realised in action. This fact is important in a medico-legal point of view. . . . .

The already important and difficult question of moral responsibility will become more delicate, under the supposition of a commencing affection of the organ of thought. When a person of hitherto irreproachable character commits a reprehensible action, the physician is disposed to plead extenuating circumstances, not because the case demands it, but for the sake of human nature, knowing all the aberrations of which it is susceptible. Experience also should be invoked, as well as reason, in deciding on so delicate a case.

I am now attending a woman, aged 42, who for a year and a half has gradually fallen into a state denoting general softening of the brain: almost entire blindness, inability to walk, semi-stupid intellect, etc., etc. Two years ago, she only felt severe and almost constant pain in the head; her general health was in other respects perfectly good, her intellect clear. Three years ago, this woman, though possessed of a competency, *committed a petty theft in a fair*. Dr. Brierre de Boismont, in his observations on General Paralysis of the Insane, states that this disease is preceded by a premonitory period, for about six or seven years, or more, before the apparent explosion of the insanity. There are *perversions of the moral and affective faculties*, without less ability on the part of the individuals presenting these changes to fulfil the duties of social life, or to perform their functions. The acts of indecency of dishonesty, of debauchery, like which there had been nothing before, are

suppressed and compensated for; then at last the patient is seized with symptoms of general paralysis.

"A person high in office," says Dr. Brierre de Boismont, "had performed the duties of his station up to the time when I was consulted; and yet the details, which were furnished to me by his wife, left no doubt that his moral and affective faculties had been for some time impaired. From having been generous and honest, he had, for more than six years, exhibited a degree of sordid avarice and unbridled licentiousness. With the progress of the disease, his avarice was manifested in mean actions; he refused to pay his debts, maintaining that he had already done so; and even purloined objects from the houses of his acquaintances. Until the last-named acts were committed, no one had suspected that his mind was disordered. . . . Some time after, I was called in consultation to see a retired public officer, whose thefts had made much noise some years previously. The particulars with which I was furnished regarding this interesting subject, made me then think that this person was labouring under the premonitory symptoms of general paralysis; I was almost sure that I should see a paralytic lunatic. The first words which he uttered in my presence showed me that the affection was far advanced. His delinquencies had been noticed eight years before; and it was only a few months ago that mental alienation was recognised."[1]

Dr. Passot has recently observed a case, in which delirium tremens appears to have been the proximate cause of the moral disturbance which supervened at a later period. Although differing in some circumstances, and although the proof *à posteriori*, that is, by the termination, has not yet been furnished, this case appears to have some resemblance to those related above. A cooper, aged 34, previously of irreproachable character, and enjoying a high reputation for honesty, was seized with delirium tremens, from which he recovered. But from this moment his conduct was deranged; he borrowed money from all quarters, and denied having ever received it. At last, after having cheated many, he fled to avoid prosecution, His intellect appeared sound; but Dr. Passot remarked, that he gave proofs of a considerable impairment of judgment, by asking persons for money from whom he had already borrowed.

These and similar examples show what difficulties are presented in this new point of view of the doctrine of moral responsibility, and how much the question requires to be elucidated by an attentive study of the precursory symptoms of encephalic affections. It may be—and there is no physiological improbability in the supposition—that an immoral or obscene action is as abrupt and unexpected an occurrence as an aberration of the senses; one of those irregular paralytic affections which almost infallibly denote an approaching disorganisation of the nervous centres. If there is a concomitance between the two occurrences, the aggregate of the pathological symptoms may be considered as furnishing evidence in favour of the non-culpability of the subject. But unfortunately the proof is often furnished only when the disease is confirmed—when the cerebral symptoms are already strongly marked. It will then be easy for the physician to trace the connexion between the previous act of the patient, and the symptoms which now appear; but will not the patient have already suffered the rigorous application of penal laws? This is a delicate problem, for the solution of which a most careful exercise of the conscience and knowledge of the physician is required. If any one is called on to give his opinion to enlighten justice regarding an infraction of morality, *committed without precedents*, in a moment when the individual is in full possession of the faculties of relation, he should express such opinion with the great reserve. It will be for him to institute a searching and severe inquiry into the previous condition of the patient, his attitudes, his sleep, his will, his memory, his sensation, etc.; and perhaps he

[1] Gazette Médicale de Paris, 1847, p. 393.

may then be able to discover some sign, from which he may deduce the irresponsibility of the subject.

The abrupt changes which may occur in a man's tastes, in his inclination, in his manner of living, in a word, in his social aspect, are worthy of attention. Modifications of this nature, when they do not appear in a slow and progressive manner, do not arise from the action of moral influences, and can only arise from a change in the nervous system. Thus it has long been remarked, that unusual gaiety in a habitually grave individual may denote the approach of an attack of apoplexy. It is the same with those who suddenly seek for noise and bustle, after having loved retirement and quietness for a great part of their life. We have known a man, aged 57, who, having up to that time led a grave and even austere life, gave himself up to the pursuit of amusements unsuited to his age, and was, a few months after, seized with sudden and complete apoplexy (*apoplexie foudroyante*). In this case, which we observed a few years ago, we were led to form an unfavourable prognosis. A man most estimable for mental endowments, and for the qualities of his heart, came one day to converse with us on subjects not relating to his health. His conversation was clear; nothing was indicated in his gait; but he had for some time complained of inaptitude for work. While we were occupied in writing a letter, we saw him rise, rummage a drawer, and open a note. This act, on the part of a person of the most polite and discreet habits, struck us forcibly. We connected it with two other circumstances which were known to us. During the revolution of February, this gentleman, holding an important post in the administration, had engaged, from the most disinterested and praiseworthy views, in public agitation, from which his mind had received a strong impression: his mother had also been attacked with senile dementia. Three months after, the patient lost his sight after violent headaches, and he subsequently died, with all the symptoms of cerebral softening. A complete change in the turn of the ideas, when it is not the result of advanced age, when it manifests itself in a short period of time, and when it cannot be traced to the action of moral influences, is very suspicious. We have known a young physician, who exhibited this phenomenon in a very marked manner, and who, a short time after, was seized with paralysis of the insane. When we knew him three years before, he was very free in his assertions, and inclined to exaggerate; but he had become discreet, and wary in his speech. His former condition, and the medium in which he had lived, shewed sufficiently that this change could not be the effect of a *progressive amendment;* we considered that there was some disease, and our opinion was ultimately confirmed.

It is conceivable, that the same psychological perturbation which changes the moral sentiments may likewise impair the sentiment of self-preservation; and hence that *suicidal melancholy* may mark the commencement of a severe affection of the brain. This disease is, moreover, very often conjoined with a lesion of the intellectual and affective faculties.

II. Premonitory Signs furnished by the Sensorial Functions. Most of these are furnished by the sense of *vision*. We will merely mention dimness, the appearance of objects as if coloured red, photophobia, etc., which may indicate threatening meningitis, as well as cerebral hyperæmia; these symptoms bear an especial relation to acute diseases of the encephalon. These signs may exist several years before the explosion of the disease. Before attacks of apoplexy, impairment of vision sometimes exists in a high degree without being known to the patients, especially when, as is most commonly the case, it is not sufficient to prevent them from seeing those who are about them. The mistake is the more easy, as this symptom may be limited to one eye; the other compensating for the weakness of its fellow. Amblyopia is a frequent symptom; sometimes there is complete blindness, as in the case of the Baron Hornestein, cited by Wepfer (*Anatomia Apoplecticorum*), who became blind three weeks before a fatal attack of apoplexy.

A valuable sign, belonging in some degree to what may be called the expression of the eyes, consists in a want of parallelism in these organs; it is not squinting, nor is it the look of hallucination. It seems pretty well defined by the following expression: *The eyes are not in the axis of the reason.* There may be certain defects in this relation pointed out between a material object and a moral fact; but those persons who are accustomed to scrutinise the human look, and to see reflected in it the different passions, will easily understand me.

The phenomenon of exaltation of special sensibility, as a precursory sign of a severe encephalic lesion, is sometimes met with. It is in this case, as in other circumstances in which it is observed, one of the most mysterious problems for the physiologist.[1] It is well known that hearing often becomes excessively acute before attacks of apoplexy. The patients, incommoded by the least noise, become irascible; they perceive distant sounds, which are unheard by those who are with them. This fineness of hearing must be distinguished from the perception of strange and imaginary sounds, which is nothing but a sensorial hallucination.

The following is a case in which disease of the brain was first indicated by enlargement of the field of vision.

Case. A painter, aged thirty-two, was admitted in 1849 into the Hôtel-Dieu at Lyons. This young man, who was possessed of some talent, had been gradually reduced to distress, partly by political disturbances, partly by other causes. A year before entering the hospital, his sight, which was previously good, acquired greater development; from his window, which opened into a very long street, he could distinguish objects and persons whom he could before neither distinguish nor even see. This circumstance troubled him, and surprised those about him. The exaltation of vision continued until August 1848, when he was seized with violent continued pains in the right parietal region; at this time there was slight weakness in the left arm. The symptoms increased till March 1849, when there was paralysis and contraction of the right arm, and blindness of the left eye. When he entered the hospital in July, the following was his condition. There was almost complete stupor; the paralysed eye was almost completely covered by the upper eyelid; there was paralysis, with contraction, of all the left side of the body; the urine and fæces were discharged involuntarily. He continued in this state until the beginning of September, when death ensued, preceded by symptoms of slow fever. The autopsy revealed partial circumscribed softening of the middle and upper part of the right hemisphere, for the extent of about two *centimètres*; the convolutions were pale and puffy; the pulp was diffluent, and of a dirty grey colour. Except the corpus callosum, which appeared soft, the rest of the cerebral substance was sound.

This phenomenon, judging from a passage in the writings of Andral, seems to have been observed in other cases. "Cases have been observed in which, for a longer or shorter period before the attack, the sight has acquired an unusual degree of fineness. The existence of these important phenomena, which are often presented by vision at a larger or shorter period before the occurrence of hæmorrhage, prove incontestably that, before the blood is effused, there is already some morbid action, either continuous or intermittent, in the brain, of which it would be important to determine the precise nature."[2]

The sense of *hearing* may present the same modifications as that of vision. Some persons are tormented with drumming in the ear, with continued or intermittent tinkling. Some believe that they hear the most strange noises. These hallucinations are by no means the constant precursors of an encephalic

[1] See the *feuilleton* of the *Gazette Médicale* for 1848, t. iii, p. 41, where several cases of exaltation of the senses are related.

[2] Andral. Clinique Médicale, tome v.

attack; they may be connected with simple perversions of the sensorial function.

Premonitory Signs furnished by the Organs of Motion and Sensation. The alterations in the *muscular functions* present great variety, from the simple hesitation which we have already noticed, to paralysis which is complete, but which, on account of its nature and its seat, we shall denominate *irregular paralysis*. It is not uncommon to observe a state of general languor which makes the patients seek for rest—for the *far niente*. Van Swieten has remarked, in treating of apoplexy: *Primò oritur languor et amor quietis et otii*. At other times, those who are about to be attacked with cerebral disease are much agitated, and expend a great amount of activity in their movements. Dr. Tessier has lately attended a lady, aged 60, who from the critical age, has been subject to attacks every month, at the period when she used to menstruate. She loses consciousness; and, after having recovered her senses, is paralysed on one side of the body, with great embarrassment of speech. These symptoms continue some days, and gradually leave her, to return at the fixed period. But some days before the new attack, this lady, though usually quiet and peaceable, exhibits much agitation; she cannot remain in her place, and those who are about her always know what this sign means. In this case, we recognise an example of *periodic nervous apoplexy*.

Impairment of muscular motion is exhibited in various degrees. It is especially remarked in the lower limbs, which seem to bend under the weight of the body, and render the gait rather unsteady. This debility is the more striking if the person be young, and has no apparent cause for it. Portal was able to prognosticate an attack of apoplexy in a gentleman apparently in perfect health, from observing a slight fixedness in the left eye and a slight weakness in the leg of the same side. *The digitus semi-mortuus*, noticed by Dr. Marshall Hall, is one of those instances of *irregular paralysis*, of which it is so important to determine the true signification. Some time ago, we saw the following case. A man, aged 54, one day called on us. In conversation, he jokingly noticed a sort of deadness which he felt in the little finger of the left hand, while the rest of the hand was able to perform its ordinary functions. We advised him to put himself under treatment: he neglected this advice, and some days after was seized with cerebral congestion, which left his faculties remarkably weakened. The *digitus semi-mortuus* has shortly since been noticed in a valuable communication from Dr. Gillet de Grandmont.[1]

Irregular paralyses, which seem to arise from exhaustion of the sources of the sensitive and motor powers, may appear under circumstances in which they do not constitute a symptom of such great importance. Such are those which sometimes follow hysterical convulsions, lead-colic, venereal abuses, etc. Here, these phenomena are connected with *transient* modifications of innervation. The suddenness of the attacks, their frequent isolation from other symptoms, their seat in parts distant from each other, while those lying between preserve the integrity of their movements, constitute the exceptional characters of those palsies which are connected with a latent alteration in the nervous centres. We must not lose sight of the difficulty of deglutition which some patients experience some time before being attacked: as well as the semi-paralysis of the vocal cords and tongue, giving rise to stammering or aphonia. The paralysis of the upper eyelids, which become œdematous, is also a sign of great value.

General sensibility may be abolished, simply diminished, or exaggerated. The two first forms almost always follow muscular paralysis; but they may

[1] Gazette Médicale, 1850, p. 400. A translation of Dr. de Grandmont's letter was given at p. 698 of the London Journal of Medicine for July 1850.

exist alone. Sensibility may be exaggerated in two forms. The patients may present hyperæsthesia, or exquisite sensibility of the whole cutaneous surface; so that the least touch troubles them. This is an increased anormal sensibility—an exaggeration of the sense of touch, corresponding to the exaltation of the sensorial faculties which we have already studied. Sensibility may also be exalted in the form of pain; and this merits our most careful attention. Violent pains, precursory of a severe cerebral lesion, have often been mistaken for neuralgia. The same is the case in treating cephalalgia, supposed to be dependent on dyspepsia: and this error is more readily fallen into, as the stomach is often disordered. The diagnosis in these cases is sometimes difficult; but the duration and violence of the pain will lead to the suspicion, that there is something more than ordinary headache, and that, although the functions of the stomach are troubled at the same time, the headache is often too intense to be accounted for by the state of that organ. The patient cannot in general endure a warm room, nor the noise made by persons about him, nor even the fatigue of agreeable conversation, without suffering an aggravation of his headache. The paroxysms are sometimes accompanied with vomiting, and sometimes with violent beating in the head. If with these symptoms we remark paleness of face and weakness of pulse, and if active measures have been employed without benefit, we are led to suspect the presence of organic lesion.[1] Painful cramps are not unfrequent. Portal has seen patients who suffered severely from cramps in the legs before an attack of apoplexy.

Cutaneous sensibility presents other singular modes of perversion. A case is related of a man who, several months before being attacked with apoplexy, experienced from time to time an absolute loss of sensibility on five or six isolated points of the skin of the thorax, each of about the size of a five-franc piece. Here the skin might be pinched without causing any pain; beyond, the sensibility was perfect. These partial abolitions of sensation were not constant. On some days there was not the least diminution of sensibility; then suddenly, and simultaneously, it was annihilated in the isolated portions. Such unusual modifications of functions directly dependent on the brain, ought to furnish us with arguments in favour of the possibility of moral and instinctive perversions, and of their dependence, not on the corruption of the moral faculty itself, but on a latent pathological condition of the organ. Hence arises the doctrine of irresponsibility.

It is in the life of relation that indicatory signs are especially to be looked for. At the initial period of severe cerebral disease, organic life reveals few or no disturbances. The symptoms which may exist under this head only acquire value in connection with those which are derived from the life of relation. The brain must be much affected to produce changes in the nutritive function. Excepting sleep, which is on the confines of animal and organic life, there is not in the latter any essential functional disturbance. In the initial period, most patients have lost the power of sleep, or, if this function be performed, it is rather a fatiguing drowsiness than refreshing sleep. The digestive functions present no other special disorder than obstinate constipation, which is often difficult to be overcome by drastics. The eyelids sometimes become œdematous; and, in some subjects, attacks are preceded by small effusions of blood, even in the tissue of the conjunctiva. The secretions are but little altered. The urine is sometimes highly albuminous; but this is a subject for further researches.

In subsequent communications, Dr. Devay proposes to treat of the etiology and treatment of incipient cerebral affections.

SURGERY.

REMOVAL OF NASAL POLYPI.

Dr. D. McRuer, of Bangor, Maine, has been in the habit, for some years, of employing the following method for the removal of gelatinous and soft polypi of the nasal passages.

A piece of catgut is passed from the nostrils to the mouth, to which is fastened a piece of soft and dry sponge, corresponding in size, when firmly compressed, to the narrowest part of the nasal passage; it is then gently drawn forwards by the posterior fauces through the nose, and, in Dr. McRuer's experience of at least ten cases, it has never failed to bring with it all the morbid growths much more effectually and easily than could possibly be accomplished by the old methods of forceps, ligature, etc. [*Trans. of Amer. Med. Assoc.*, vol. iii, 1850, p. 361.]

DISPLACEMENT OF HARD CATARACT BY LATERAL TRACTION.

Professor Pancoast, of Philadelphia, describes the following operation for the removal of hard cataracts, which he says he has practised in about twenty cases during the last two years, with no permanent failure, and with very little, or generally no apparent pain or inflammation.

"The removal of the opaque lens by the common couching process, when it is found too hard to admit of division without rolling on its axis, is, I believe, admitted to be greatly superior, in its general results, to any other process. But the success attending this mode of operation is not by any means so great as could be desired. In the hands of the most skilful operators, complete success is not obtained, perhaps, in more than six cases out of seven, the general average being infinitely below this. The causes of failure may be said to consist in the subsequent re-elevation of the cataract; in the violent rupture of the delicate mechanical connexions of the inner tunics of the ball made at the time of operation; in the injury of the iris and ciliary processes inflicted by the needle, or caused by the pressure of the lens, couched improperly so as to press against these sensitive and probably muscular structures; in a severe disorganising inflammation speedily following the operation, or one of a more chronic character, which finally leaves the retina amaurotic.

"I keep the iris, for several days previous to the operation, thoroughly dilated by the application of belladonna. I puncture the sclerotic coat at a distance nearly equal to the diameter of the lens behind the margin of the cornea.

"The needle I employ is modelled from that of Scarpa, but with a longer and more sudden curve, and reduced to the smallest size allowable, in order to have it to pass through the sclerotic coat, so that I may, with its diminished bulk, disturb as little as possible the interior structures of the ball. A curve of the needle, almost amounting to a rectangular turn, I deem indispensable. The needle, after it has entered the hyaloid humour, is carried forward in the usual manner, so as to break between the edge of the lens and the ciliary body into the aqueous chamber, at a point where the hyaloid tunic forms alone, in all probability, the posterior wall of that chamber; and in doing this the ciliary processes or the iris need not be touched. The needle, after being made to divide the capsule of the lens in the usual manner, is to have its hooked part sunk into the centre of the lens. The lens, instead of being pressed down as in the ordinary process of couching, is to be gradually drawn horizontally backwards, through the same track by which the needle has passed, to the place of puncture made in the sclerotic coat. The handle is then to be depressed, and the needle detached from the eye. By this process the eye is as little disturbed as possible, and the lens rests in the interior of

the hyaloid tunic, and not in contact with either one of the more delicate structures of the ball, the iris, the ciliary body, or the retina, and with no tendency to resume its old position.

"In the same way, and with the same success, I have several times displaced secondary capsular cataracts. If the lens proves to be soft, it cannot, of course, be displaced, but may readily, with the same needle, be broken up in its bed. Occasionally, where the lens has been large, I have failed in drawing it horizontally backwards, in the gap made by the needle, and have been obliged to couch it in the usual manner. But in the hard cataracts of old persons, the kind that we have perhaps most frequently to deal with, and which are usually diminished in size, the displacement by this process, with a needle of the kind above described, will be found an easy and satisfactory operation." [*Transactions of American Medical Association*, vol. iii, 1850, p. 365.]

OVARIOTOMY: RULES FOR THE OPERATION.

Mr. J. G. Wilson lays down the following rules for the operation. 1. To make as small an incision as possible. 2. To draw out only as much of the cyst as could be extracted readily, and without displacement of the other contents of the abdomen. 3. To endeavour to keep the wound always filled with the cyst, so that neither air nor fluid should be admitted into the cavity of the abdomen. 4. To cut off the cyst, not close to the wound, but from one and a half to two inches beyond it, so that when the portion of cyst has been removed, the cut margins could be carefully examined, and the vessels secured. 5. To secure each vessel in the cut margin of the cyst separately by fine silk, and to cut off both ends close, so as to have no ligature hanging from the wound. 6. To close the external wound as quickly as possible. [*Prov. Med. and Surg. Journ.* Jan. 22, 1851.]

TANNIN IN OPHTHALMIC DISEASES.

M. Hairion of Louvain has a very high opinion of Tannin in eye-diseases. The following remarks by him are quoted from the *Journal de Médecine et de Chirurgie Pratiques* for October 1850.

Tannin has, probably, been only used in catarrhal ophthalmia, in the proportion of one part to 120 of water; but the want of efficacy of this solution has made it fall into almost complete disuse. For more than five months, I have employed tannin in the form of pommade, in thick mucilage, in fine powder, and especially in concentrated solution (one part to three of water). The affections in which it has proved most successful have been acute and chronic blennorrhœa, œdematous swelling of the conjunctivæ, vegetating granulations, vascular and ulcerative affections of the cornea, and especially pannus, which has been cured, in some cases, with astonishing rapidity.

Tannin has been justly styled the styptic *par excellence;* its local mechanico-chemical action renders it highly useful in ophthalmology, whether to retard muco-purulent effusion of the conjunctiva, to combat the relaxation of that membrane, to obtain the obliteration of cellulo-vascular productions, or to diminish dilated or newly-formed vessels; or, by producing coagulation of the plastic fluids, to accelerate the cicatrisation of ulcers of the cornea, strengthen its softened tissue, and prevent its projection or laceration.

This remedy is free from the objections which may be urged against other astringents. Its application is not painful, it produces no severe reaction, and leaves no caustic marks, nor indelible incrustations.

Tannin has been employed in the circumstances indicated above, frequently with signal success, sometimes without advantage, never with injury.

MATERIA MEDICA AND PHARMACY.

DUTCH LIQUID AS A LOCAL ANÆSTHETIC.

M. Aran has recently communicated to the Academy of Medicine in Paris a paper on Local Anæsthesia. The following are his conclusions, given in the *Gazette Médicale de Paris* for 23rd November 1850.

1. All general anæsthetics (the ethers, chloroform, Dutch liquid, aldehyde, benzine, etc.) possess also the property of inducing local anæsthesia.

2. The energy of the local anæsthetic power is in an inverse relation to the volatility of the substance. This explains why Dutch liquid is superior, as a local anæsthetic, to all others, why chloroform is better than ether, and acetic ether than the other ethers.

3. Some anæsthetics, as the ethers, aldehyde, and benzine, produce no irritation when applied to the skin ; others, again, are more or less irritating. Chloroform produces, in small quantity, a burning sensation, and may even produce vesication, if the quantity be greater, and contact more prolonged. Dutch liquid is irritant ; but infinitely less so than chloroform.

4. The local anæsthetic action of Dutch liquid continues longer than that of other substances, even when only from fifteen to thirty drops are applied to a painful part. It only produces slight stimulation, and has a slight ethereal odour, more agreeable than that of the ethers, aldehyde, or benzine.

5. To obtain local anæsthesia, from fifteen to thirty drops are to be dropped on the painful part, and the whole covered with a wet compress and a piece of waxed cloth (or oiled-silk). This succeeds in most cases, where local anæsthesia is indicated.

ELIMINATION OF ARSENIC IN ARSENICAL CACHEXIA.

The *Brit. and For. Med.-Chi. Review* (Jan. 1851) quotes the following remarks of M. Hannon, from the *Revue Médicale*, vol. i. 1850, p. 754.

By Arsenical Cachexia is meant that special deterioration of the economy, which those who have absorbed into their system a certain quantity of arsenic undergo, and which is of more frequent occurrence than is supposed. The health of many workmen in the trades in which arsenic is employed is thus injured, as is that of children by sweetmeats coloured by arsenite of copper. So, too, after the injurious employment of arsenic in medicine, and the treatment of cases of poisoning by emetics and antidotes, the patient is never cured until the arsenic has been expelled from the economy. It will remain in the system, until it has been rendered soluble by combination with some body, and thus eliminated. M. Hannon believes that *sal ammoniac* effects its elimination, as completely as the iodide of potassium has been shown by Melsens to eliminate lead and mercury. He believes, too, that arsenic may be prevented from accumulating in the economy by combining this substance with it.

ALOIN : THE CATHARTIC PRINCIPLE OF ALOES.

The Messrs. T. and H. Smith of Edinburgh (to whom pharmacy is indebted for many discoveries and improvements), have succeeded in separating from aloes a crystalline substance possessing the characteristic effects of the crude drug ; and, which from a perusal of the paper before us, we think the authors correctly regard as the cathartic principle of aloes. The history of this discovery is given in the *Edinburgh Monthly Journal* for February 1851 ; and an account of the chemical characters of Aloin is contained in a paper by Dr. Stenhouse in the *London, Edinburgh, and Dublin Philosophical Magazine* for Dec. 1850. Some of the chemical properties of aloin are very remarkable.

The action of doses of aloin on the human body is thus described by the

Messrs. Smith : "The first trial was made with half a grain. It acted twelve hours after being taken, in the manner that so characteristically distinguishes the action of aloes. The same quantity was again given to two healthy young men, with a similar result ; except that in one about twenty-fours elapsed before its operation. In the next two cases, one grain failed to act ; but in one of these, the dose having been increased to two grains, a very strong operation was the consequence. In a case where four grains were given, the person, a patient of Dr. Robertson, Physician to the Edinburgh Royal Infirmary, had been getting one-quarter grain doses of elaterium with little effect. The operation in this case was rather violent. In numerous other cases in which it was tried, it invariably operated in doses of from one to two grains. The result of these trials was the removal from our minds of every doubt of the crystalline body yielded by the aloes being that on which its cathartic action depended, being, in fact, the active principle of the drug."

DORVAULT ON IODINE AND ITS COMPOUNDS.

M. Dorvault is a Parisian drug-vendor, and not a physician ; a circumstance which greatly lessens the value of his monograph, in so far as it relates to the therapeutic value of Iodine and its compounds. Nevertheless, it has merit as a compilation ; and there are in it some good remarks upon the chemical and pharmaceutical departments of the subject : and these are pretty fully noticed in the *British and Foreign Medico-Chirurgical Review* for January 1851, p. 91.

The *modus operandi of Iodine* is thus announced by the author : "Iodine is a specific fluidifier, and every morbid affection recognising for its cause or effect a humoral coagulation, more or less plainly indicates its employment." It has this advantage over the alkaline fluidifiers, that, while it fluidifies the fibrin, it spares the globules.

The *Iodide of Potassium*, M. Dorvault thinks, has none of the defects, and embodies all the excellencies of iodine. He believes that it is in this form that it exists in the marine plants and animals in which it is found." The system, having once given admission to the iodide, discharges it with remarkable rapidity and completeness. Scharlau, of Stettin, recovered daily from the urine 345 of the 350 centigrammes administered. Kramer found that, after employing it for fifty days, six suffered from its elimination. Marchal (de Calvi) found it in the urine in from twenty-five to sixty minutes, after only a grain had been given. Of 15 grains, 0·883 parts were recovered from the urine in thirty-six hours, leaving only 0·117 to be accounted for."

NEW PREPARATION OF THE PHOSPHATE OF IRON.

At a late meeting of the Medical Society of London, Dr. Routh exhibited two specimens—one solid, the other fluid—of phosphate of iron dissolved in metabasic phosphoric acid in a boiling state, and allowed to cool. The solution was of a semi-transparent, greenish, or slaty hue. If exposed to the air for a day, it hardened ; but could be made at once into pills by being mixed with liquorice powder or flour. The compound was soluble in any proportion of water, and free from any nauseous inky taste. It appeared better adapted than any other preparations of iron for cases of anæmia and debility brought on by venereal or other excesses, over-study, and other depressing diseases in which there was a prevalence of nervous symptoms, and a large quantity of phosphates voided by the urine. It did not gripe or constipate. The dose was gr. i or ij three times a day. [Abridged from *Medical Times*, Jan. 25, 1851.]

THE HOSPITALS OF LONDON. No. III.

BY DR. CORMACK AND DR. SEMPLE, ASSISTED BY NUMEROUS REPORTERS.

BETHLEM HOSPITAL.

PHYSICIANS. Dr. Monro ; Sir A. Morison.
SURGEON. W. Lawrence, Esq.
RESIDENT MEDICAL OFFICER. Dr. W. Wood.

THIS ancient institution (one of the first, if not the oldest, asylum for lunatics in Europe) was founded in 1247, during the reign of Henry III, by Simon Fitzmary, a sheriff of London, at Bishopsgate, when it was designated the Priory of Bethlehem. At the dissolution of the religious houses, the property was seized by Henry VIII, who in 1547 granted the Priory, with all its revenues, to the Corporation of London ; from which time, it was appropriated as a hospital for the cure of lunatics. Owing to the limited income the institution possessed, the usefulness of this charity was necessarily circumscribed, until the year 1675 ; when, by the liberality of benevolent individuals, a splendid building was erected in Moorfields for the reception of 152 insane patients. Tradition reports that the design was taken from the Tuileries ; which so incensed the "grande monarque", Louis XIV, when he heard his regal château had been made the model of a madhouse in London, that he ordered a plan of St. James's palace to be taken for offices of the meanest nature. Over the gates of the old hospital, constructed in Moorfields, the two celebrated statues were placed of Melancholy and Raving Madness, sculptured by Caius Gabriel Cibber, the father of Colley Cibber the comedian ; these are still seen in the vestibule of the modern structure in St. George's Fields, Lambeth.

Notwithstanding the addition of wings to the original building in Moorfields, it was found inadequate to the increasing claims made for admission within its walls ; hence, in 1812, the first stone of the present edifice was laid, to contain 198 lunatics. In August 1815, the new hospital, being completed, was opened for the reception of patients ; nevertheless, like the old institution in the city of London, it was soon found inadequate for the wants of an increasing population. The charity having now, however, ample funds at their disposal, the governors resolved to build additional dormitories for 166 inmates ; these were accordingly commenced in July 1838, and finished about two years afterwards. Although the accommodation, afforded in the new hospital, was thus made considerably greater than previously, two other wings, chiefly for convalescent patients, were added in 1845 ; whereby, also, a better classification of the lunatics could be accomplished. Along with these additions, the central dome, which now towers above all the neighbouring buildings, was erected, to serve as a chapel for patients and residents.

In consequence of the various additions thus made to Bethlem Hospital, the institution is capable of accommodating 450 inmates ; although the average number of patients, usually under treatment, seldom exceeds 400, including the criminal and the incurable lunatics.

The medical staff of the hospital consists of two physicians, viz., Dr. Monro and Sir Alexander Morison ; one surgeon, Mr. Lawrence ; and a resident medical officer, Dr. Wood, who alone resides on the premises. Consequently, during twenty-two out of the twenty-four hours of every day, on that gentleman rests the responsibility of superintending the medical treatment ordered by his superior officers, for so large a population ; as there are neither house-

surgeons nor resident pupils, as in many foreign lunatic asylums, or even some English establishments.

Bethlem is a hospital for the cure of mental diseases, not an asylum for lunatics. Although a limited number of incurable insane patients now reside within its walls, in consequence of a valuable estate in Lincolnshire having been left for the express purpose of maintaining incurable and dangerous lunatics, a large proportion of the patients under treatment are recent cases, whose mental malady has not been of long continuance; and no lunatic is admitted who has continued more than one year insane. In consequence of this regulation, the annual number of admissions is generally considerable: and the character of the maladies, affecting the patients under treatment, is more acute, and often exhibits very different types of disease from those usually manifested by the inmates of county lunatic asylums.

During the year 1850, the number of curable lunatic patients admitted into Bethlem Hospital, was 344, of whom 135 were males, and 209 females; thus giving a preponderance of 74 in the latter sex, or 54 per hundred. The number of patients discharged cured during the same period, amounted to 197, consisting of 74 men and 123 women; being at the rate of 57 per cent. of cures, which forms a high ratio, and is considerably beyond the amount discharged convalescent in previous years. Amongst the curable patients, the number of deaths was 31, which exceeded the usual average. This arose chiefly from the circumstance, that last year many individuals were received into the house almost in a dying state, through motives of charity. Much relief was thus given to the relatives and families of the afflicted sufferers, as well as comfort to the patients themselves. Besides the 31 deaths now enumerated, four incurable and six criminal lunatics died in 1850; so that forty-one is the total number of fatal cases during the past year.

Speaking generally, 13 of the total deaths were classified as the immediate consequence of disease of the head and nervous system, three of which arose from general paralysis. This fact deserves notice, seeing that the malady is considered of less frequent occurrence in England than on the continent; especially if London be compared with Paris. Sixteen patients died from affections of the thoracic organs; of whom six were carried off by phthisis, and three by that rare form of disease,—except amongst the insane,—gangrene of the lungs. Respecting this unusual morbid change of structure in the respiratory organs, it may be interesting to mention, that the three instances all occurred in male patients; and as two had been only four weeks in the hospital, the other about eight months, the mental disease, consequently, had not likely been of long standing; whilst neither of the patients were old men, one being 45, another 41, and the third in his thirtieth year. *Exhaustion* is reported as the cause of death in nine cases. This expression is too indefinite; and might, we think, be generally superseded by more precise phraseology in a hospital report regarding disease amongst lunatics.

Another interesting feature connected with the insane patients admitted during the last year into Bethlem Hospital, is *the apparent cause which produced mental disease.* This constitutes an important subject of investigation in all complaints, but especially in those of the mind; and as minute inquiries are always made respecting the above point, when patients enter this institution, much curious and instructive information is often obtained.

As it would be incompatible with the present brief sketch of Bethlem Hospital, to enumerate every particular cause producing insanity in the three hundred and forty-four patients admitted during the year 1850, a short summary, with a few illustrations, will suffice to show the chief influences which appeared to produce the attacks of mental alienation. Speaking generally, one half of the cases, in both sexes, were ascertained to have arisen from moral causes. Anxiety appearing the most frequent influence;

twenty-six women and twenty-two men being so classed. Grief at the death of friends was reported to have produced insanity in eighteen females, but in only two men. Love caused madness in twelve females; but not a single instance occurred amongst the male patients; whilst religion was assigned as the apparent cause of mental disease in eight women and in six men. Various other moral agents might be also enumerated, which, however instructive, would be tedious to particularise; nevertheless, one or two curious examples of the powerful effect often produced upon weak human minds by transitory influences may be mentioned, as they show how easily the mental faculties are disordered, and sometimes even completely upset, by temporary impressions, doubtless strongly acting at the time upon the nervous system, and a susceptible constitution. Thus, two men became mad from the fear of being attacked by cholera, and one from political excitement. Two women, on the other hand, were deprived of reason from living with insane persons; one from attending a singing-class; another female lost her senses from terror at the revolutionary disturbances in Paris; whilst a fifth became insane from the excitement of travelling, for the first time, by a railway.

Amongst the physical causes producing insanity, intemperance was reported as the most frequent, especially in men, nine cases having been met with in that sex, while eight occurred amongst the female patients, although the latter were more numerous. Bodily illness produced madness in thirteen women, but only five instances occurred amongst the male inmates. Eight cases of puerperal insanity were admitted, and three arose from lactation; four from change of life; two from uterine disturbance; and one female was reported to have gone mad from her recent marriage. Again, amongst the male patients, four were stated to have become lunatics from solitary sexual excess; three from exposure to a hot sun; one from the disappearance of an accustomed eruption; another in consequence of an attack of cholera; whilst one poor fellow became insane from severe sea-sickness. Lastly, amongst the whole 135 male lunatics admitted, 39 cases were ascertained to have hereditary tendency to insanity, which makes about 29 per cent.; whereas, amongst the 209 female patients, 67 exhibited hereditary tendency to mania, being at the rate of 32 per cent. on the admissions; thus proving that mental diseases, besides being more frequent in women, are likewise transmitted to the offspring in a higher proportion amongst them than in the opposite sex.

In addition to the above summary of the chief causes which apparently produced mental alienation in the various individuals admitted into Bethlem Hospital, it may be interesting to mention, especially as the frequently severe character of the cases is thereby manifested, that more than half the male patients, or 76 of the 135 admitted, were classed as violent cases, most being likewise dangerous either to others or themselves. Farther, amongst the 209 female lunatics also admitted during 1850, nearly one-half, or 100, were enumerated in the same category, of whom 90 were decidedly dangerous lunatics. It is also worthy of special notice, that 58, or nearly one-half of the male patients received, were classed as suicidal; of whom 14 had actually endeavoured to destroy themselves previous to their admission. Again, amongst the 209 female lunatics, almost one half, or 103, were ascertained to be suicidal patients, of whom 28 had attempted suicide prior to becoming inmates of this establishment.

The above interesting facts are now briefly mentioned, not only to shew the forms of mental disease generally met with in the curable wards of Bethlem Hospital, but also to prove, that unlike most public receptacles for lunatics, particularly county asylums, this institution is, in great part, appropriated for the reception of recent cases of insanity, and therefore constitutes a hospital for the cure of insane patients, rather than a refuge for

the hopeless victims of that terrible calamity. Hence, those who have remained more than one year within its walls, without receiving benefit, are then discharged as uncured, in order to be replaced by others more recently attacked with insanity. Although relatives may be sometimes inconvenienced by having their afflicted friends thus sent home before they are convalescent, and with perhaps slighter hopes of improvement than existed previous to admission, it ought to be always remembered that, during one year at least, and occasionally even for fifteen or eighteen months, such patients have been maintained and treated gratuitously; and although they no longer receive the benefits of this charity, other fellow-creatures equally, or even more severely afflicted, then occupy the recently evacuated dormitories. By this arrangement, a larger number of lunatics are annually received, than could be otherwise admitted; and in this way the utility of the institution becomes more extensively diffused. As every English county now has, or ought to possess, an asylum for the reception of its lunatic poor, the regulations in force at Bethlem Hospital render its benefits more generally useful, notwithstanding instances may occasionally occur, where a rigid adherence to the spirit of the rules may prove inconvenient to individuals.

Bethlem, being an hospital appropriated chiefly for recent cases of insanity, whilst the criminal and incurable lunatic patients also supply numerous illustrations of chronic and protracted instances of mental disease, supplies an excellent field for the study and investigation of mania in every variety. Until recently, medical students could no where else in the metropolis obtain clinical instruction and practical knowledge respecting the treatment of insanity, except at this hospital. But even here, owing to the very high fee charged for permission to attend the physicians, and as only three pupils could be entered at the same period, the doors of the institution became almost wholly shut to the general body of the profession; so that few students, excepting those specially intending to treat mental diseases, were induced to avail themselves of the means of instruction here afforded to them.

About nine years ago, Dr. Webster, then a governor of the hospital, brought the subject of allowing medical pupils greater facilities, when attending in the wards of the institution, before the managing authorities. Considerable discussion ensued upon his proposition, which it now seems wholly unnecessary to detail. Nevertheless, the agitation, thus commenced, ended ultimately in throwing open the portals of this large charity to all medical students who might feel anxious to obtain knowledge respecting the treatment of insanity, and to witness the practice of the physicians; the admission fee for each term—extending to about four months—being reduced to three guineas; whilst, in the summer season, clinical lectures are given by one of the medical officers. During last year, Dr. Monro lectured to the pupils, of whom generally about ten attended very regularly. In the ensuing summer term, Sir A. Morison will probably undertake that duty, as he did during 1849. Hence, no professional person can complain that he is unable to learn the nature, symptoms, treatment, and pathology of mania; for not only Bethlem Hospital, but St. Luke's, and the Hanwell Asylum, are now accessible to properly qualified applicants.

Notwithstanding these facilities for studying insanity, the numbers likely to take advantage of the ample opportunities at present available, will not, probably, be numerous, until the licensing medical corporations require from all aspirants for their honours, practical proofs that they are conversant with diseases of the mind as well as of the body. Formerly, it was sometimes said to be useless to insist on candidates for diplomas from the Colleges possessing any knowledge of mental diseases, as no place was open for obtaining such

knowledge. Now, others even assert it to be unnecessary to enter hospitals for the insane, as the Colleges do not examine on insanity, and there is plenty to learn besides. Such reasoning may be agreeable to the inactive student; but it only shews the necessity which exists of medical colleges, and public bodies, altering their system, especially in reference to medical officers entering the army and the East India service. Indeed, a rumour prevails, that an intention exists of requiring from the future surgeons appointed to the Honourable Company, a certificate of having attended at a public lunatic institution, where they have had proper opportunities of acquiring an adequate knowledge of the management of mental diseases. This would be a very judicious proceeding; and however necessary for those filling military medical appointments, it is still more essential for civil practitioners; especially as they are liable, at any time, to be called upon to attend cases of madness, and sometimes on an emergency; which duty they should be as much qualified to undertake, as to treat any severe attack of fever, an accident, or accouchement. Besides this, if both legally and medically conversant with the subject of insanity, the physician or surgeon would be then fully prepared to enter courts of justice, when called as a witness in cases *de lunatico inquirendo*. He would then be able both to speak confidently, as well as scientifically, respecting the symptoms and condition of the individual under investigation, instead of being sometimes brow-beaten by astute barristers, who even consider it a great triumph if they can invalidate the evidence of "doctors", by making them give obscure answers to difficult questions, and so puzzle the court and jury through mystifications. This an experienced practitioner ought to be fully qualified to clear up or explain, with credit to himself, and with advantage to the afflicted lunatic.

Elaborate and varied statistical data are annually prepared, containing many instructive particulars respecting the curable patients under treatment, during the year. These tables were commenced, in their present form, in 1843, by Dr. Webster, who arranged the plan adopted, and compiled the different returns for that and the succeeding year, when they were printed for the use of the governors, along with the Report of the General Committee of Management. Exactly parallel statements have been drawn up regularly ever since they were commenced, more recently by the resident medical officer, Dr. Wood, and these are now distributed to the governors along with the Physicians' Annual Report. As it would be tedious to enumerate the different subjects embraced in these official documents—amounting to thirty-five in number,—the reader need be only now informed, that they contain, amongst other particulars, the condition of the inmates admitted, their former occupations, the assigned causes of their disease, and whether dangerous, violent, or suicidal patients. The symptoms and treatment, also the apparent cause of death, the numbers discharged uncured, or sent home convalescent, are carefully recorded. The influence which age, season of the year, duration of the attack previous to admission, the patients' domestic condition, degree of education, nativity, and religious persuasion, have exercised upon the disease, are likewise registered; besides other data of much value to the student and medical practitioner. As these tables have now been continued, on the same model, for eight consecutive years, and already form a large collection of important information, they will every day become of greater value to psychologists.

UNIVERSITY COLLEGE HOSPITAL.

The following is the Medical Staff of University College Hospital.

Physicians. Dr. W. H. Walshe, *elected* 1849 ; Dr. Parkes, *elected* 1849 ; Dr. Garrod, *elected* 1850.

Assistant-Physicians. Dr. Jenner, *elected* 1849 ; Dr. Hare, *elected* 1850.

Obstetric Physician. Dr. Murphy, *elected* 1842.

Surgeons. R. Quain, Esq., *elected* 1842 ; John Erichsen, Esq., *elected* 1850.

Assistant-Surgeons. John Marshall, Esq., *elected* 1848 ; W. Cadge, Esq., *elected* 1850.

Consulting Ophthalmic Surgeon. R. Quain, Esq., *elected* 1850.

Ophthalmic Surgeon. T. Wharton Jones, Esq., *elected* 1850.

Dental Surgeon. Durancé George, Esq., *elected* 1844.

Apothecary. J. T. Clover, Esq., *elected* 1848.

The Obstetric Department, which is presided over by Dr. Murphy, is devoted to the superintendence and care of Pregnant Women until they are delivered ; to the treatment of Diseases of the Womb and its appendages ; and to the Diseases of Children.

Three days in the week—Monday, Wednesday, and Friday—are set apart for the purpose of giving letters for attendance to pregnant women. Their names, residences, ages, etc. are entered according to the following formula.

No.	Date.	Name	Age.	Residence.	Health.	Catamenia.			No. of Children.	Miscarriages.	Letter sent to	General observations.
						Age at first appearance.	Interval.	Last appearance.				
1	Dec. 27	A.B.	25	15, Warren-st.	Good	15	Four weeks.	April 22	6	2	Mr. L.	

To the woman is then given a letter, directed to the gentleman who is appointed to attend to her. If he is willing to do so, he gives the patient one-half of the sheet for her guidance, and keeps the other ; if not, the letter is brought back to be directed to another. When the woman is delivered, another formula is filled up, and returned to be entered on the register.

No.	Date of delivery.	Duration of labour.	Placenta expelled.	Child.					Mother.	Attended by.	Duration of pregnancy.	Remarks.
				Position.	Sex.	Living.	Dead.	Putrid.				
1	Jan. 27	10 hours	10 min.	1st V.	M.	1	0	0	1	Mr. L.	280 days	

By this means, with other more usual particulars, an important collection of facts in reference to the duration of pregnancy may be obtained. The interval between the last appearances of the menses and the delivery of the patient is always accurately noted, when the information can be accurately obtained. The women are all attended at their own houses : they receive medicines for a fortnight after delivery. The number of patients who received letters during the year 1850 was 788.

Two obstetric assistants are appointed for periods of six months. The senior aids Dr. Murphy in the treatment of diseases of the womb, both in the out and in the in-patients. He also assists, when called upon, in cases of difficult labour. The junior assistant is chiefly engaged with the midwifery cases. He is first called upon in any difficulty in delivery, when, if necessary, he sends for the senior assistant, or for Dr. Murphy. He assists in keeping the register of midwifery patients, and in the performance of any minor operations that may be necessary.

Patients afflicted with diseases of the womb, of whom there are about 300 in the year, are attended as out or as in-patients; the latter occupying a ward in the hospital devoted to these complaints. The out-patients attend on Tuesdays, Thursdays, and Saturdays. Thursday is the day for the private examination of uterine diseases. A large proportion, at least 70 per cent., are cases of chronic inflammation in one form or another. Their frequency is nearly in the following order: 1. Inflammation and ulceration of the os and cervix uteri (about 60). 2. Inflammation of the ovaries, generally the left (about 30). 3. Inflammation of the body of the womb, accompanied by highly hysterical symptoms (10). Each of these forms may merge into the other, but they generally observe the above order; inflammation of the neck extending to the ovary and body of the womb, and inflammation of the ovary to the body: but the reverse, extension of the inflammation of the body or the uterus or of the ovary to the os and cervix uteri, has not been observed; though there is no reason why this should not happen. The speculum is used in all cases of inflammation and ulceration of the os and cervix uteri. The local remedies employed are chiefly nitrate of silver, and sometimes potassa fusa.

Inflammation of the ovaries is generally detected by pressing the inguinal space with the fingers of opposite hands, one being passed into the vagina, the other behind the linea ilio-pectinea. These patients are generally sterile. The proportion of prostitutes has not been ascertained; but ovarian inflammation seems by no means confined to them.

Of other diseases, displacements of the womb are next in frequency. Prolapsus is the most common; then retroversion or retroflexion, anteversion, and sometimes anteflexion. In the diagnosis of these affections, Dr. Simpson's sound is used, except when pregnancy is suspected. In the treatment, Dr. Murphy sometimes uses no instrument, contenting himself with replacing the uterus by the hand. In other instances (of retroversion) he passes a gum-elastic ring-pessary back to the *cul-de-sac* of the vagina, so that, when the sound is withdrawn, the womb cannot fall so far back as before. The uterine supporter is seldom used, having been found to cause inflammation.

Next in order of frequency are fibrous tumours, with a few cases of polypus, carcinoma, and, very rarely, corroding ulcer and cauliflower excrescence.

Disordered menstruation is so frequently only a symptom of other diseases, that it is difficult to separate it. For instance, dysmenorrhœa is the constant symptom of stricture of the cervix uteri, caused by a spasmodic contraction of the fibres between it and the body of the uterus. This is generally the result of chronic inflammation, but sometimes it is congenital. It is relieved on the same principle as stricture of the urethra, by dilatation with metallic bougies.

Venereal cases in the mother are sent to the surgeon. Copper blotches, and other venereal eruptions, are often met with about the nates and testes of infants.

The diseases of children are chiefly those of the skin, scrofula, and chronic disorders, the result of innutrition. The acute diseases, inflammation and fever, are less numerous, and the patients only attend at the commencement of the attack, as they require the aid of a dispensary, where the child may be attended at home. The number of these is about 200 in the year.

NORTH LONDON EYE INFIRMARY.

Consulting Surgeon. John Dalrymple, Esq.
Physician. Dr. Twining.
Surgeons. White Cooper, Esq.; G. D. Pollock, Esq.; John Pyle, Esq.; H. B. Norman, Esq.
Apothecary. Mr. Burcham.

An interesting example of sudden recovery of sight, after an operation for cataract, occurred recently in a patient of Mr. White Cooper. An elderly female, of rheumatic constitution, had undergone three operations for solution; but, as a hard nucleus still obstructed the pupil, she had no sight. It was intended to depress this nucleus, but accident rendered such a step unnecessary; for, whilst doing some household work, the woman felt an acute pain shoot through the eye and head, and instantly saw. The obstructing body had fallen down behind the iris, leaving the pupil clear. For ten days all objects appeared tinged with blue; but, by quiet and some treatment, this symptom of retinal irritation passed away, and she now sees well. In 1849, Mr. Cooper saw a somewhat similar case. A cataract had been extracted from the eye of a surgeon, and, in passing through the pupil, it had left a small portion of transparent soft circumference behind; the section healed kindly, but the soft matter becoming opaque, blocked up the pupil. The sight being thus very imperfect, he slipped when sitting down, about three weeks after the operation, and fell backwards, striking his head with force against a door. For a minute he was stunned; but, on recovering, was agreeably surprised at the clearness with which objects appeared. As in the former case, the obstructing fragments had been displaced, leaving the pupil clear. Mr. Cooper has now under his care a good example of strabismus convergens, caused by an ulcer on the cornea. A little girl, six years of age, had a small inflamed ulcer on the lower half of the left cornea. When first seen, and for a week subsequently, the eye was perfectly straight, but the ulcer became exceedingly sensitive, and the eye turned in to avoid the friction of the lid on the abraded surface. A drop of castor oil was directed to be placed between the lids, and the usual treatment was adopted; but although the ulcer has been healed for some weeks, the squint remains. Had the ulcer been in the centre of the cornea, the strabismus might have arisen from the natural effort to overcome the obstruction to vision; but it is below the margin of the pupil, and consequently the sight is not interfered with.

There have been an unusual number of rheumatic and catarrhal inflammations this winter, frequently accompanied with ulceration. Bark and soda, with or without colchicum, and mild local stimulants, were the most efficacious measures.

REPORTS OF SOCIETIES.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Tuesday, January 28, 1851.

Samuel Solly, Esq., Vice-President, in the Chair.

Case in which the Cæsarean Section was performed; with Remarks on the Peculiar Sources of Danger attendant on the Operation. By Charles West, M.D. The patient was a young woman, aged 27, a patient of Mr. Wren of Brownlow Street, whose health had always been indifferent, but whose person was not apparently deformed, and who reached the end of her first pregnancy without manifesting any symptoms especially calling attention to the state of her osseous system, with the exception of pains of a rheumatic character, and difficulty in walking, which last became very great during the last two months of her pregnancy. When labour came on, at the end of the full period, the existence of extreme pelvic deformity was at once ascertained by Mr. Wren, in whose opinion, as well as in that of Dr. West, Dr. Murphy, and Dr. Ramsbotham, the performance of the Cæsarean section was indicated. It was accordingly performed by Mr. Skey, fourteen hours after the commencement of labour, and eight hours after the rupture of the membranes; uterine action having been feeble from the first, and having almost ceased since the escape of the liquor amnii. The patient was, by her own desire, subjected to the influence of chloroform before the operation was begun: no difficulty was experienced in its performance, and a living female child was extracted. Very formidable hæmorrhage followed the removal of the placenta; and the subsequent contractions of the uterus were very tardy. The patient was left in a state of great exhaustion, from which she never rallied, and died in 108½ hours after operation, apparently from the conjoint effects of the hæmorrhage during the operation, and of the shock to the nervous system. The treatment consisted in the administration of stimulants and nourishment, both by the mouth and in enemata, and the patient was kept almost throughout under the influence of opium. The body, on examination after death, presented no evidence of serous inflammation; but the uterine wound was gaping widely, and even that of the abdominal parietes was but partially closed. The pelvis presented, in a most marked degree, all the characteristics of that deformity which is produced by mollities ossium; the pubic bones being projected into a beak 1·2 inch in length, the width of the pubic arch being reduced to ·6 of an inch, and the distance between the tuberosities of the ischia to 1·2 inch.

Dr. West then proceeded to point out the causes of the high rate of mortality among the mothers in cases of Cæsarean section, which in hospitals abroad was 79 per cent., and in this country 85·4 or 87·5 per cent. The causes were referred to four heads, and illustrated by reference to 134 fatal cases, in which the body was examined after death. The four heads were as follows: 1. Hæmorrhage; which proceeds from a source different to that whence bleeding takes place in any other operation, and which is not capable of being arrested by the same means as suppress it under ordinary circumstances. 2. The shock inflicted on the nervous system, as well by the violent interference with the most important process that ever goes on in the organism in the same limited time, as by the injury to a part so important, and so richly supplied with nerves, as the uterus of a parturient woman. 3. The hazard inseparable from extensive injury to the peritoneum, when unblunted in its sympathies, and unaltered in its texture, as it is in cases of ovarian and other tumours, for the removal of which a similar exposure of the abdominal cavity is sometimes practised. 4. The infliction of a wound

on the uterus, at a time when, in the ordinary course of things, the processes which nature is prepared to carry on in it consist in the disintegration and removal of the tissue—processes the very reverse to those essential to the repair of injury. The author concluded that, these sources of danger being so serious, and so beyond the power of art to prevent, the rule which forbids the performance of the Cæsarean section, wherever there is a reasonable probability of accomplishing delivery by the natural passages, is founded on solid grounds, and ought to be adhered to.

Tuesday, February 11, 1851.

Dr. Addison, President, in the Chair.

Case of Cæsarean Section. By Henry Oldham, M.D. The subject of this case was a rickety, deformed girl, aged 23, unmarried, pregnant with her first child, and seven months gone in gestation when first seen by Dr. Oldham. On examination, the pelvis was found to be reduced to two inches in its conjugate diameter, and the uterus was much anteverted. The membranes were punctured for the induction of premature labour, in a few days after she was seen, September 23rd, 1850. On the following morning, the left arm was found in the vagina, but labour did not come on until nine A.M. on the 26th. In twelve hours, the os uteri was dilated, and then some attempts to deliver her were made. The child could not be turned; but, by drawing down the protruding arm, which, from commencing decomposition, soon gave way, and pressing the abdomen from below, the head was brought over the brim, and was at once perforated. For four hours, the crochet was employed, both inside and outside the head, the bones of which were completely torn up, but without drawing it through the brim. At this time, a new impediment was found to have arisen, from the descent of the right hand and a foot, by the side of the collapsed head, into the pelvic brim; and, on watching the effect of labour pains, all these parts were felt to be squeezed together in the narrow inlet of the pelvis, each preventing the other's descent. It was attempted to bring down either the foot or hand; but only the slippery tips of each could be touched, and they could not be moved. The patient had now been seventeen hours in labour, and it became a question for serious consideration and consultation, whether she would be able to sustain the necessary efforts for her delivery, and whether it would not be for her benefit to perform the Cæsarean section before exhaustion came on, which at length was determined on. The operation was performed by Mr. Poland, without difficulty, and with little hæmorrhage, the patient being under the influence of chloroform. The incision, five inches long, was slightly curved, and a full-sized seven months' fœtus was removed, and afterwards the placenta and membranes. For two days the patient did well; but then exhaustion came on, and she died. While she lived, she was kept under the influence of opium, and was sustained by simple cold drinks. On post-mortem examination, there were some slight traces of peritonitis near the uterus. The external opening was closed, and its edges adherent, but the uterine incision was gaping. The larger omentum was indurated and inflamed, and so drawn across the uterus, above the incision, as to prevent any discharge from the latter organ escaping into the peritoneal cavity.

Two practical questions were suggested by this case. 1st. What was the best plan to attempt to follow out in the delivery at first? 2nd. Were the complications such as to justify the Cæsarean section? With respect to the first question, one of two plans of treatment might have been adopted: 1. To induce labour, and deliver by craniotomy; 2. To allow her to go to term, and then perform the Cæsarean section. In determining in favour of the former, the author was guided by the great probability—with a conjugate diameter of two inches—of being able to deliver with the crotchet, and he considered that his inability to do so arose from the complex presentation. With reference to the

second, he was induced to have recourse to the Cæsarean section, from a conviction that the patient would probably sink under the prolonged efforts at delivery; and a case was related which occurred in the Lying-in Charity at Guy's, under Dr. Ashwell, where a woman with a far less contracted pelvis died undelivered, after the powerful and sustained efforts to relieve her. It was remarked that the girl had but a feeble constitution, which would ill support so hard a trial of its powers; and the condition of the vagina was particularly noticed as retaining the marks of early age, being structurally weak and easily lacerable, and most unfavourable for a long craniotomy operation. Under these circumstances the Cæsarean section offered a speedy and sure, instead of a prolonged and doubtful delivery. It was not yet forbidden from exhaustion, or any signs of inflammation.; on the score of suffering it contrasted most favourably with persistence in the use of the crotchet; and, upon the whole, it was judged to offer a better chance of ultimate success. The curve in the incision was suggested to catch the outline of the muscular fibres on the inner surface of the uterus, and so favour the closure of the wound. The scanty hæmorrhage during the operation was in a measure accounted for by the uterus being at the seventh instead of the ninth month, by the placenta being attached to the posterior wall, and the uterus being opened low down towards the cervix, where the veins were less developed. Chloroform was said to be a gain in every way, and the after-treatment by opium appeared satisfactory.

[The personal tone of the discussion makes it difficult to give with fairness to all parties a condensed account; and for that reason we are forced to omit it.]

MEDICAL SOCIETY OF LONDON.

December 28, 1850,

J. Risdon Bennett, M.D., President, in the Chair.

Physiological Properties of Picrotoxine. By R. Mortimer Glover, M.D. The author commenced by detailing seven experiments, the animals experimented on being dogs, a she-ass, a pigeon, a frog, a rabbit, and a gold fish. The results in each experiment, and the *post-mortem* appearances, were alike, namely, retrograde movements, shown in a slight degree by convulsive twitches of the eye, head, neck, and shoulders backwards, and in an extreme degree by a regular forced retrogression, salivation, and general tremors, bloody stools, laborious breathing, rapid action of the heart, and opisthotonos. The autopsies revealed total extinction of the muscular irritability, with great heat of the muscular fibres, the thermometer rising to 115 degrees; irritability of heart, more so of the auricles than of the ventricles, both cavities being distended with black fluid blood; the lungs slightly congested; the stomach and intestines showing marks of irritation; great congestion of the brain and its membranes, especially the lower portions, the cerebellum, corpora quadrigemina, and upper part of the spinal cord, with much bloody serum in the ventricles. The dose of picrotoxine given to the dogs varied from one to two scruples; to the ass, 100 grains; to the pigeon, 4 grains; to the frog, 5 grains; and to the rabbit, 10 grains; 5 grains were placed in the water containing the gold fish, but the picrotoxine is very insoluble in water. In all these experiments it was either given by the mouth, or inserted under the skin of the axilla or groin. The author next proceeded to compare the results of his experiments with those made by M. Flourens in the removal of various parts of the brain, especially in the corpora quadrigemina and cerebellum. The resemblance, he remarked, was very striking. To prove this, a quotation was made from Cuvier's report to the Institute on Flourens' experiments, and the following conclusions were drawn by the author as the legitimate deductions from the results

of his experiments: 1. Picrotoxine has the power of determining peculiar movements and effects very similar to those described by M. Flourens as resulting from sections of the cerebellum, and perhaps of the corpora quadrigemina. He did not think, however, that the animals in his experiments were blind until just before death, if then, as in the cases where Flourens cut away the corpora quadrigemina. The iris was certainly in some cases contractile, until the symptoms became very severe, when the pupil was enormously dilated. 2. Picrotoxine also acts powerfully on the spinal cord, and generally is a narcotico-acrid poison. 3. It is not, for one of these active principles, so very energetic, that is to say, in such small doses, like conia, aconitina, etc., although a most terrible poison. 4. The animal temperature was much increased in some of these experiments, forming, in this respect, a great contrast with some facts Dr. G. observed several years ago, showing the great diminution of temperature undergone by animals slowly poisoned by the chloride and bromide of olefiant gas, chloroform, bromoform, etc. How far the increase of temperature was owing to the excitement of the nervous system, he (Dr. G.) would not decide. The peculiar movements caused by picrotoxine, Dr. Glover thought, were neither reflex nor voluntary, but should be considered a third kind of motion.

On the Assimilative Force in relation to Hypertrophy and Atrophy. By Alexander Henry, M.D. The following is the summary of the author's remarks on hypertrophy. 1. In all cases of hypertrophy, we have to consider the assimilative force of the tissues as the essential element. 2. In certain instances, this force seems sufficiently intense to appropriate a steadily supplied increase of blood, without being heightened by any stimulus. 3. In several tissues in the higher animals, and in man, hypertrophy takes place only under the stimulus of functional exercise; and an excessive supply of blood will not produce hypertrophy, unless the assimilative power of the part be thus stimulated. In atrophy, the assimilative force was considered to be sometimes impaired from want of exercise, and sometimes from being exhausted by over-exertion. Defect of it was also considered by Dr. Henry, (following in a great measure the views of Dr. Hodgkin), to be an important pathological element in fever.

Treatment of Permanent Stricture of the Urethia. By Robert Wade, Esq. Nothing very new was contained in the paper; and nothing remarkable was elicited by the discussion.

February 1, 1851.

J. Risdon Bennett, M.D., President, in the Chair.

Use and Abuse of the Speculum. By R. Greenhalgh, Esq. The author had examined a thousand women with the speculum within three years. In

a fifth of that number he had found red granulating surfaces, varying in size from a small pea to half-a-crown ; and in some instances they bled when touched. In two cases, in each of which the cervix uteri was enlarged, puffy, and somewhat tender to the touch, in part covered with a large, red, and apparently granulating surface, the os uteri admitted the top of the finger ; to both the potassa fusa was applied, and was followed by peritonitis ; the patients ultimately recovered. Mr. Greenhalgh considered that he had used the speculum far too often, and that in reality it ought rarely to be employed. In most cases of uterine sores he preferred vaginal injections to cauterisations ; and in all he thought the cure was chiefly to be obtained by constitutional remedies, such as steel with ammonia, the mineral acids, the shower bath, and hot and cold hip baths.

Dr. Crisp recollected the opposition which followed the introduction of the stethoscope, upon the ground of indelicacy. The objection was valid against both instruments when they were abused, but both were employed with advantage in proper cases.

Dr. H. Bennet thought that the frequency with which Mr. G. had used the speculum was not justifiable. At the Western Dispensary, with which he had been connected, the cases in which the symptoms justified the use of the speculum were, in about three years, only 300 ; being in the proportion of about 120 in the 4000 or 5000 women who annually presented themselves for treatment at that institution. The potassa would of course do mischief when misapplied ; it cured chronic cases by substituting acute for chronic inflammation.

Dr. Murphy expressed regret at the unfair spirit in which the speculum controversy had lately been carried on. He agreed with Dr. Bennet in thinking that the speculum ought only to be used when a very strong probability existed that there was uterine disease requiring its employment. Evidence of this could generally be obtained ; and the indiscriminate investigations of Mr. Greenhalgh were not to be commended. "Ulceration of the cervix", about which so much had been said, Dr. M. defined to be "a florid, red, circumscribed granular spot, such as is found in the conjunctiva or the throat. The surface is but little raised, on account of the delicacy of the membrane, and paucity of cellular tissue ; but its elevation is more and more marked as the disease advances." The neck of the uterus becomes indurated, and increased in volume, causing general disturbance of the health, which cannot be fully met without local treatment. Constitutional measures should be applied at the same time.

Mr. Greenhalgh stated, in reply to the above and various other speeches addressed to the Society, that he had used the speculum so extensively only for the purpose of testing its value, and testing the truth of the statements which had been made regarding the frequency of ulceration of the cervix uteri. He had not made it a matter of gain ; having, with half-a-dozen exceptions, used it only on gratuitous patients.

On Gonorrhœa. By John Chippendale, Esq.

February 15, 1851.

J. Risdon Bennett, M.D., President, in the Chair.

Anatomy of the Urethra. Mr. Hancock made the following communication :—Assisted by Mr. Hogg, he had examincd, microscopically, the structures surrounding the urethra. He found that the urethra itself was not muscular, but closely invested by organic muscular fibres continuous with the muscular coat of the bladder, which consisted of two layers, an internal and an external. The external passes forwards, and extends over the outside of the prostate gland ; the internal, on the contrary, accom-

panies the mucous lining through the prostrate, forming an involuntary muscular covering to the urethra in its passage through the gland. The membranous portion of the urethra is next closely invested by these muscular fibres, which cannot be mistaken for any portion of Wilson's, Guthrie's, or Santorini's muscles, the latter being voluntary, and presenting the usual striated appearance under the microscope, whilst the former are involuntary and nucleated. Continued forwards, they reach the bulb, where they divide, the one part being continued onwards to the orifice of the urethra, lying between it and the corpus spongiosum, whilst the other passes on the outer surface of the corpus spongiosum, separating it from its fibrous investment, to which the fibres adhere pretty closely. These latter are also continued forward to the orifice of the urethra, and, in their course, invest the spongy portion of the bulb, urethra, and glans penis, entering very largely into the formation of that peculiar structure found at the orifice of the urethra, and which appears to consist almost entirely of involuntary muscle and elastic cellular tissue, forming an additional sphincter muscle to those usually described as met with in various parts of the body. It will thus be seen that the corpus spongiosum urethræ lies between two layers of involuntary muscle, the one separating it from the urethra, the other from its fibrous covering ; an arrangement, doubtless, exerting considerable influence over the expulsion of the blood from the corpus spongiosum when erection of the organ is no longer required, as well as over the emission of urine and the seminal fluid. After the meeting, Mr. Hancock exhibited, under the microscope, specimens of the muscular tissue just described.

Morale and Medicine in Connexion with Phthisis. By Theophilus Thompson, M.D. [This paper will appear as an original article in this volume.]

MISCELLANEOUS INTELLIGENCE.

Convalescent Hospital at Carshalton. The Carshalton Hospital, near London, was founded six or eight years ago, by Dr. Forbes and benevolent persons, for the purpose of affording to the sick poor, and to those especially who had been discharged from the London hospitals, a temporary asylum, where they might have the advantages of good pure air, wholesome food, and a properly regulated regimen, before they returned to their laborious trades, and were again exposed to the injurious influences which surround the homes of the London artizans.

The rules of the establishment are very simple. A subscriber's letter entitles a patient to the benefits of the hospital, provided he be declared a fit subject by the London committee. A selection is necessarily obliged to be made, as the hospital is of limited size, and its funds are at present small. If the patient be eligible, he is then sent to Carshalton free of expense, and is kept there for one month. Medical attendance is provided ; but the chief remedial measures relied upon are exercise in the pure air, a good diet, and the regular habits enforced in the hospital. The improvement in the health of the London workman is sometimes almost incredible : we have frequently heard individuals who had returned from Carshalton speak of it and of the benefit they received there, in terms of the deepest gratitude.

The advantages of such an institution as this are obvious. Our London hospitals are generally obliged to leave their work half done. The acute disease may be cured, the broken bone united, or the operation-wound neatly healed ; but beyond this the case is left very much to itself. A patient cannot be kept in hospital till his constitution has thoroughly rallied from the shock, and till the nutritive functions are again performed with perfect regu-

larity and vigour. He is obliged to be sent forth, too often to return at once to a miserable and filthy den, and at once to endure, with an exhausted frame, the fatigues of, it may be, an unhealthy occupation. No wonder is it, that in this way the unfortunate artizan often sinks into a state of permanent ill-health ; and when he is next admitted to the hospital, it is with an incurable disease.

No blame attaches to the medical officers of our London hospitals for this premature discharge of patients ; it is impossible to retain convalescent persons in the wards when numberless applicants are clamouring for their turn. The hospital has done its part of the work, and probably done it well ; but something else is wanted to confirm and ratify this work, and to secure it from the chance of its having been done in vain. The idea of a Convalescent Hospital, a few miles from London, to which such patients can be sent, was an obvious one. It has been well worked out on a small scale at Carshalton, and, as we have already intimated, the results have been most satisfactory.

It is now proposed to extend the application and the benefits of this institution. A new hospital is in course of erection, on a piece of ground generously given to the governors by Lord Ellesmere, and the number of patients will be considerably increased. To do this, however, funds are wanted ; and it is with a view of entreating our professional brethren not to remain inactive when a scheme of such obvious utility is impeded for want of money, that we have now brought before them the nature and circumstances of this hospital.

It would be a most desirable thing to bring this Convalescent Asylum into connexion with the great London hospitals. Bartholomew's, or Guy's, or University College, should *own*, as it were, a certain number of beds, which should be kept occupied with such convalescent patients as were deemed likely to be most benefited by country air and country regimen. A small subscription from each hospital would nearly support the Carshalton Asylum, which would then become *ex officio* and completely, what it is now only partially and incidentally, a great sanitary depôt, in which the cures begun elsewhere might be perfected, and secured from relapse. Bartholomew's and Guy's would not diminish the actual good effected in their wards, if they devoted some part of their enormous incomes to providing for their convalescent patients the most effectual means for making permanent the good which has been effected. [From *Medical Times*, February 22, 1851.]

The First-year Student upon his arrival in London. "Where shall he live ? What shall he do ? Who will become his friends and future companions ?

"The moral position of the student, during the session that is now about to open, must needs be a subject of painful anxiety to those parents who know well that the time has arrived when it is fitting and necessary that even their favourite son shall face the temptations, and begin to take his share in the great business of the world. What will then be his conduct ? Will it reflect honour on them, and be creditable to himself ?—or will some evil genius throw its malignant influence around him, and seduce him from the paths of rectitude into those of idleness and dissipation, where he will squander his means, revel in vice and folly, and bring gray hairs with sorrow to the grave ? Will he escape, uncontaminated, the snares which notoriously lie in wait for the youthful traveller when he has left his parental hearth, and is wandering through the highways and bye-ways—the broad streets and narrow alleys—of a great and over-peopled city, in which wealth and poverty, luxury and starvation, virtue and vice, seem huddled together in striking and revolting contrast ? How will he return to the home of his fathers ?

"These are questions of deep and solemn import, which at this moment make the life-blood quiver in many a mother's heart. It behoves us now,

therefore, to view the student's life under its moral aspect. And, first, his place of residence should be judiciously chosen. There cannot be a question that the best policy will be to board in a respectable private family,—if possible, in the house of a physician or surgeon, who will superintend his studies, and whose society will always be instructive, and bear upon the great object he has in contemplation. Lodgings, the best of them, are dreary solitudes, which the brightest fire on a winter's night will hardly cheer up into anything like domestic comfort. 'I am never domesticated', said Robert Southey, 'in lodgings; the hearth is unhallowed; the Penates do not abide there.' The student, with all his home associations fresh about him, feels this, and soon leaves his solitary fire-side to enjoy the gaieties of the theatre, the licentiousness of the tavern, or the society of new acquaintances, with whom he is tempted to smoke cigars, drink punch, and tell merry stories—'pleasant, but wrong'—until the hour arrives when Hamlet's ghost, in the shape of a policeman in blue armour, 'sniffs the morning air,' and meeting him in the deserted street, perhaps 'marshals him the way that he should go.' Habits of irregularity and intemperance are hereby engendered, which are incompatible with study, and which never would occur or be tolerated in a private family. But however important for his personal comfort the place of his abode may be, the choice of his new companions is of infinitely greater consequence to his future happiness, for this is the initiatory step which will govern for good or for evil all his future movements. The purest stream may become contaminated by running through poisoned ores. Vicious habits are more contagious than the leprosy of old, and disfigure the mind, more than that Eastern plague ever did the body. Once infected, there is no escape. Beware, therefore, of new acquaintances. The lustre of a young man's honour soon becomes tarnished in an impure atmosphere. Use caution and discretion in the selection of your friends, and cultivate an intimacy only with those who are of studious and temperate habits, and who can, directly or indirectly, in conversation suggest new ideas, or impart information. For the mind, even in its hours of recreation, should be as active as the swallow on its wing. There are many young men who exhibit no apparent or outward vices, whose society, nevertheless, it would be well to avoid. Such are the following:—We would avoid those who are gay, thoughtless, and prodigal, who lavish their money foolishly away, and whose lodging-house cupboards are miniature wine stores and gin palaces. We would avoid fashionably-dressed youths, who profess to understand and be fond of horses and dogs, and the mysteries of the race-course and the ring, and who leave the hospital for the livery-stable, to associate with grooms, pugilists, horse-breakers, and dog-fanciers. We would avoid those who delight in billiard-playing, whist, écarté, and games of chance, their proficiency in which has been purchased at the expense of their professional education. We would avoid men who habitually haunt the theatre and the tavern, who 'vex the drowsy ear of night' with their uproarious mirth, and go forth to their class-room next morning with faces pale, and cadaverous, and suffused with the fumes of the previous night's debauch. We have, too, a prejudice against any young man whom we may meet with moustache on his lip, and 'imperial' on his chin, elbowing his way along the street with a student's cap upon his head, and a cigar reeking in his mouth. Their cigar is the symbol of the tap-room and the wine-cellar. We would avoid associating with men who are much richer than ourselves, for we could not prudently compete with them in their expenses, and it should always be our pride never to be ashamed of an honourable poverty. We would, also, for our own peace of mind, avoid over-talkative men—everlasting chatterers—the magpies of debating-societies. We know many such, but they have no health in them. What says the immortal Shakespeare? 'Let not the creaking of shoes, or the rustling of silks, betray thy poor heart to woman;

keep thy foot out of brothels, thy hand out of plackets,[1] thy pen from lenders' books, and defy the foul fiend.' " [Dr. S. BUSHNAN'S *Address to Medical Students*. London: October 1850.]

ROYAL MEDICAL SOCIETY OF EDINBURGH. The annual dinner of this important Society, now in the 114th year of its existence, took place in the Archer's Hall, Edinburgh, on February 20. In addition to a large attendance of ordinary members, there were present the Presidents of the Royal Colleges of Physicians and Surgeons, several of the Medical Professors of the University, besides other distinguished members of the Profession in Edinburgh. Among others, were Professors Christison, Syme, Balfour, and Hughes Bennett; Drs. John Conolly of Hanwell, Dr. R. M. Glover of Newcastle, Dr. Adams of Banchory, Mr. J. F. Macfarlan, the Treasurer of the Society, and Mr. A. Gifford, law-agent. Mr. Wolley, as Senior President, occupied the chair; and Dr. Alexander Christison (son of Professor Christison), Mr. Sanderson, and Mr. Murchison, officiated as *croupiers*. After the usual loyal toasts, the Chairman proposed "Prosperity to the Medical Society." He referred to the benefits which the Society, from the earliest period of its history to the present time, had conferred on the medical profession. Many of the great men, who had been educated in the Edinburgh Medical School, had owed more of their advantages to the important training which its debates afforded, than even to their more regular academical studies. Mr. Wolley, in further alluding to the project just now before the Society, of removing to a more commodious and more advantageously placed hall than the one which it at present occupied, expressed his confidence that the past and present usefulness of the Society would prove the guarantee of its future prosperity; and that although it had often, and with some truth, been called an ancient Society, yet, so far as its prospects were concerned, it had only just completed the period of its youth, and was now entering on its maturity. Mr. Sanderson next proposed, "The University of Edinburgh and the Professors." Dr. Christison, in replying, expressed the pleasure which he felt in conveying to the Society the assurance of lasting interest which the Professors felt in its welfare, and their willingness to cooperate in its objects. "The prosperity of the Royal College of Physicians, and the health of Dr. Simpson," were next proposed by Dr. Alexander Christison. Dr. Simpson replied, expressing his sense of the great benefits which he himself personally had received from the Society in the early part of his career. He concluded by proposing the health of the "Senior President." Professor Christison next proposed the health of Dr. Conolly; after which, Dr. Conolly having responded, various other toasts were given, and the Society separated at a late hour, much gratified with the whole proceedings of the evening.

EPIDEMIOLOGY *v.* PATHOLOGY. Epidemiology is in the ascendant! At the commencement of this session, the Pathological Society offered to pay rent to the Royal Medical and Chirurgical Society for permission to meet in their rooms in Berners-street; but the Council declined the proposal. This, it now appears, arose from no feeling of dignity on the part of the executive, as subsequently they granted the gratuitous use of their apartments to a semi-scientific association—the Epidemiological Society. We are not able to explain the conduct of the Council; but *it requires explanation*, more particularly if it be true, as the *Medical Times* alleges, that an "upholsterer and chair-maker" has been proposed as a member of the new Society which has been so hospitably housed by the rulers of the Royal Medical and Chirurgical.

THE FOTHERGILLIAN GOLD MEDAL of the Medical Society of London, for the best essay on Phthisis, has been awarded to DR. RICHARD PAYNE COTTON, Assistant-Physician to the Hospital for Consumption, Brompton.

[1] "Plackets," an old word signifying *petticoats*.

APPOINTMENTS.

James, W. W., Esq., elected Surgeon to the Exeter Dispensary, in the room of W. P. Kingdon, Esq., resigned.

Parsey, Dr. W. H., late Assistant Medical Officer of the Devon County Lunatic Asylum, to be Medical Superintendent to the Warwick County Asylum.

Smith, Andrew, M.D., Deputy Inspector-General of Hospitals, elected Inspector-General of Hospitals, and Superintendent to the Army Medical Department, in the room of Sir James McGrigor, resigned.

St. Mary's Hospital, Paddington. The following gentlemen have been selected:—Physicians—Drs. Alderson, Chambers, and Sibson. Surgeons—Messrs. Coulson, Lane, and Ure. Physician-Accoucheur—Dr. Tyler Smith. Surgeon-Accoucheur—Mr. I. B. Brown. Ophthalmic Surgeon—Mr. White Cooper. Aural Surgeon, Mr. Toynbee.

OBITUARY.

Audubon, M. J. J., the distinguished naturalist, at his residence near New York, aged 76, on 27th January.

Fletcher, Dr. Ralph, late Consulting Surgeon to the Gloucester General Hospital, at his residence in Gloucester, aged 70, on 8th February.

Langenbeck, M., Professor of Surgery at Göttingen, aged 75, lately.

Mackness, Dr. James, at Hastings, aged 46, on 8th February.

Naegele, Dr., Professor of Midwifery at Heidelberg, aged 72, lately.

Thorpe, R., Esq., Consulting Surgeon to the Royal Infirmary at Manchester, aged 64, on 21st January.

TO CORRESPONDENTS.

To the Editor of the London Journal of Medicine.

24th February, 1851.

Sir,—In a "Paper on Continued Fever", by Dr. Humphry Sandwith, published in the London Journal of Medicine for the present month, is the following passage: "On the other hand, Dr. William Jenner himself admits, that occasionally, though very rarely, in typhoid fever with the rose rash, the follicular lesion is wanting". So far as I am aware, during four years' daily attendance at the London Fever Hospital, I saw not a single exception to the rule, that rose spots are diagnostic of typhoid fever, that is to say, of an affection having for its anatomical character disease of Peyer's patches, and that the mulberry rash is diagnostic of typhus fever; I mean just as far diagnostic of those diseases as are the eruptions of measles, and of scarlet fever diagnostic of those two diseases. I may add, that the experience of 1850 fully bore out the law I attempted to establish in vol. xxxiii of the *Medico-Chirurgical Transactions*, that the poison of typhoid fever, of typhus, and of relapsing fever, respectively produce only disease identical in essential characters with that from which the poison generating the new disease itself sprung. By inserting this in your ably conducted Journal, you will oblige,

Yours obediently, W. Jenner.

8, *Albany-street, Regent's Park.*

St. Thomas's Hospital. From the length of the account of this hospital, we have been obliged to postpone it to next month.

Our Cotemporaries, when they quote original articles from our pages, ought to name the Journal to which they are indebted. Dr. R. Quain's paper on the Stethometer (wood-cuts included) was transferred to the *Lancet* and *Medical Gazette*, but there was no reference to the London Journal of Medicine. By another species of inadvertence, our youthful brother the *Institute* reprints one of Dr. C. J. B. Williams's papers on the Physical Examination of the Abdomen, stating that it is from the *Dublin Journal of Medicine!*

Foreign Editors and Authors are requested to deposit copies of their works with M. Victor Masson of Paris, or with any of the booksellers in Germany in correspondence with Messrs. Williams and Norgate, of Henrietta Street, Covent Garden, London. In all cases they ought to be addressed, distinctly, "To the Editors of the London Journal of Medicine, Richards' Printing Office, 37, Great Queen Street, Lincoln's Inn Fields, London."

LONDON JOURNAL OF MEDICINE,

A MONTHLY

Record of the Medical Sciences.

APRIL 1851.—No. XXVIII.

ORIGINAL COMMUNICATIONS.

ACCOUNT OF A CASE OF SPONTANEOUS COLLAPSE OF THE ANTRUM.

By W. WHITE COOPER, Esq., F.R.C.S.; Senior Surgeon to the North London Eye Infirmary, and to the Artillery Company; Ophthalmic Surgeon to St. Mary's Hospital.

(Read before the Medical Society of London, March 1, 1851.)

THERE are few gentlemen engaged in the practice of our profession, who do not, once at least during their lives, meet with cases of so anomalous a character as to set at defiance all the recognised rules of science and of art. We are in the habit of terming such cases *unique;* but it would probably be more correct to regard them as examples of disease occurring only at rare intervals, and then forgotten. Notwithstanding the vast accumulations of published observations which bear testimony to the diligence and pains-taking industry of our predecessors, they can hold but an insignificant relation to the mass of knowledge which has been lost through not being placed on record. Sir Benjamin Brodie has well remarked, in one of his Introductory Discourses, that "the best part of every man's knowledge is that which he has acquired for himself, and which he can only to a limited extent communicate to others. You will spend your lives in endeavouring to add to your stores of information; you will from day to day obtain a clearer and deeper insight into the phenomena of disease; you will die at last, and three-fourths of your knowledge will die with you; and then others will run the same course. Our sciences are indeed progressive; but how much more rapid would their progress be, if all the knowledge that experience gives could be preserved."[1]

I have been led to these reflections, by the signal failure which has attended my endeavours to obtain information from published authorities on the case I am about to relate.

CASE. On the 22nd March, 1849, I was consulted by Margaret Ryan, aged 25, a strongly-built young Irish woman, who complained of a flow of tears over the cheek. Her appearance was remarkable; there was a deep depression of a purplish hue between the side of the nose and the malar bone of the left side, precisely as if a portion of the superior

[1] BRODIE, Sir B. C. Introductory Discourse, 1843.

maxillary bone had been removed. It was bounded superiorly by the inferior margin of the orbit, which partook of the depression; inferiorly by the base of the alveolar process; externally by the malar process of the superior maxillary bone and the malar bone, and mesially by the nose. The distance from the bridge of the nose to the deepest part of the depression was one inch and four tenths, or nearly one inch and a half; on the right side, the admeasurement between corresponding points was barely an inch. The angle of the mouth on the affected side was slightly directed upwards, which became more marked when she smiled. There was slight *stillicidium lachrymarum.*

History. Until seven years previously, her face had been perfectly symmetrical; but about that time she first perceived a dusky mark beneath the left eye, unattended with pain or weakness of the organ. This dusky appearance gradually extended down the face by the side of the nose, and, after a time, some flattening of the cheek became apparent. Gradually and almost imperceptibly this increased, still without any sort of pain or uneasiness, until the face had assumed the form described; but it was not until a week before I saw her that there were symptoms of discomfort in the eye and cheek, when she felt shooting pains, and was teased by the watering of the eye.

On examining her mouth, the teeth of the left side were found *in situ*, but greatly decayed, and the gums were in an unhealthy state. There was not, however, any alteration in form, either of the alveolar process or the hard palate, neither was there any obstruction in the corresponding nostril, though the patient thought it rather drier than the other. The finger recognised a deep depression in the situation of the antrum, but there was no indication either of loss of substance or destruction of bone; the cheek seemed simply to have sunk.

Thinking it possible that the decayed teeth might have something to do with these changes, I recommended extraction of the cuspid and bicuspid. This was kindly done by Mr. Alfred Canton, but not without considerable difficulty, and the fangs presented that rough appearance so indicative of periostitis. Mild astringents were prescribed for the eye, and soon after I lost sight of the patient for a time.

On the 6th June, 1850, she again applied to me, on account of the stillicidium lachrymarum, which had recommenced. No alteration in the cheek was apparent, with the exception perhaps of a somewhat darker hue of the integuments. She stated, that with trifling exceptions, she had been free from pain, and that the trickling of the tears had only returned quite recently; it subsided in a fortnight under mild astringents.

She again called upon me on the 4th of last February. A decided increase of the depression was now visible; the whole anterior wall of the maxillary sinus seemed to have sunk, causing considerable deformity. The depth of the depression continued the same, but the superficies was greater; the integuments were rather more adherent to the bone, giving a puckered appearance to the cheek; the nostril was free and unaltered in form, but thinner and less firm than the opposite, as if slightly atrophied; the alveolar process retained its figure. She informed me that she had enjoyed the best of health during the past twelve months, and had nothing to complain of, except an occasional weeping of the eye. Her present condition is that above-described.

Remarks. Until the middle of the seventeenth century, when the maxillary sinus was first fully described by our countryman, Nathaniel Highmore,[1] little was known of this osseous cavity, and less of the diseases to which it is subject. Since that time, however, able writers and good observers have not been wanting, and Bordenave,[2] Runge,[3] Jourdain,[4] Desault,[5] Deschamps,[6] Weinhold,[7] and Gensoul,[8] have left on record much

valuable information on the subject of diseases of the antrum; I have not, however, succeeded in finding in the works of those authors, or elsewhere, a satisfactory description of the affection under which my patient labours. The only observation, indeed, directly bearing on the point, with which I am acquainted, is in Otto's *Compendium of Pathological Anatomy*.[1] "The maxillary sinus," says he, "is either entirely wanting, or very small, according to the imperfect development of the bones; still, however, although these are perfect, the cavities may be much diminished, or even entirely destroyed by great contraction of the bones." And in a note he adds: "I at least have seen it in several cases."

It is far from easy to trace or to offer a satisfactory explanation of the changes which have taken place in the case under consideration; they partake perhaps most of the character of atrophy, as if some check had been given to the due nutrition of the parts, or to the deposition of new matter, in place of that removed in the ordinary course of life. Though the effects produced by the irritation of decayed teeth are usually the very opposite to that here presented to our notice, yet the distinct evidence of irritation borne by the diseased condition of the teeth extracted must not be lost sight of, and, in the absence of any more definite exciting cause, may possibly have originated the peculiar morbid action which has been set up; but that such an amount of alteration should have taken place without pain, and with such trifling inconvenience, is truly remarkable. It must be distinctly borne in mind that there was no sinking in of the alveolar process; *that* stood out in bold relief in consequence of the depression above, so that the diminution of the cheek was quite independent of any contraction arising from loss of teeth.

The patient was seen by Mr. Fergusson on the 28th of March, 1849, and he favoured me with the following note.

"My dear Sir,—This is a curious case; I never saw one like it. I am disposed to think that contraction of the antrum is going on, and that the anterior wall is drawing inwards so as to cause the alteration in the symmetry of the face. I cannot suggest anything.

"Yours very faithfully, Wm. Fergusson."

Mr. Stanley and Mr. Edwin Saunders have also been kind enough to make a very careful examination of the woman's face; and the former gentleman stated to me, that neither in the numerous museums which he had inspected, nor in the course of his very extensive researches with reference to diseases of bones, had he met with a similar case.

[Postscript. During the discussion which followed the reading of this paper, it was suggested by Mr. Edwin Canton, that the condition of the face might have resulted from the development of a tumour from the floor of the antrum, adherent to the anterior wall; the growth of this being arrested, and a curative process set up, it would, as it shrank, draw the anterior wall after it. Mr. Chippendale thought it might have arisen from the outlet of the antrum having been so stopped as to render the cavity air-tight, so that the pressure of the external atmosphere caused collapse of the bones. Mr. Pilcher mentioned instances in which he had seen appearances similar to those described follow a congenital want of symmetry, and also a case of a vascular tumour, which springing from the antrum, had caused absorption of the anterior wall, and when compressed, gave rise to the appearance of a depression in the cheek. Lastly, it was suggested, that some disease may have attacked the superior maxillary nerve, or certain of its branches, and that the atrophied condition of the parts was the result.]

A PRACTICAL ANALYSIS OF SEVENTY CASES OF INFLAMMATORY, FUNCTIONAL, AND STRUCTURAL DISEASE OF THE HEART.

By S. SCOTT ALISON, M.D., Licentiate of the Royal College of Physicians of London.

The examples of Heart-disease of which I propose, in this communication, to give some account, are divisible into inflammatory, functional, and organic. The line has been drawn as correctly as the nature of the subject, and the difficulty of always forming an accurate diagnosis, would permit. Examples of disease may have been regarded as simply functional, which may have comprised some organic lesion; and, on the other hand, cases may have appeared to involve rather more organic change than was really present. Nevertheless, I am confident that, on the whole, the return is reasonably correct. Every exertion was made to ascertain the facts of each case, which have been faithfully recorded. Structural disease is, for the most part, the result of inflammatory or of functional disease; and it is difficult to say exactly where the one ceases, and the other commences. In making a division, I have preferred being directed rather by prominent and well marked features, than by very minute observation or elaborate reasoning.

The total number of cases of heart-disease, of which this paper treats, is seventy. Of these, three were inflammatory; twenty-five were functional; forty-two were structural.

I. INFLAMMATORY DISEASES OF THE HEART.

Respecting the cases of inflammation, a few words will suffice. They are only three in number.

Case I. This was a boy, four years of age. The form of disease was advanced pericarditis, with copious sero-purulent effusion in the pericardium, and very abundant woolly-looking deposit of lymph upon the whole exterior surface of the heart. The aortic orifice was somewhat contracted and corrugated. The patient, eleven weeks before, had been attacked with scarlet fever.[1] Anasarca occurred three weeks after. Inflammation of the left lung and pleura had likewise supervened, causing hepatisation and copious effusion into the pleura of sero-purulent fluid. The patient had been an out-door patient at a medical institution up to within a few days of his death; and he came under my care when it was too late to adopt treatment with any hope of a favourable result. This case was published in the *Medical Gazette*.[1]

Case II. This was a boy, six years old. The symptoms led me to believe that a moderate amount of inflammation of the pericardium had taken place. On the fifth day of an attack of scarlet fever, the patient was seized with severe pain in the region of the heart, and

[1] Medical Gazette, February 1845.

with violent palpitation. A small bleeding afforded great relief; and the patient recovered. Pains in the joints and anasarca followed. Recovery took place; but the impulse of the heart was long after observed to be abnormally great.[1]

Case III. A girl, ten years of age, largely made, was seized with acute rheumatism. She had had a similar attack about a year before; for which I treated her, but without venesection. The heart did not become implicated. On this occasion, she did not apply to me for several days after the commencement of the attack; and she had not been seen above once by a medical attendant. On my first examination, the "to and fro" rubbing sound was distinctly heard, and a loud sawing systolic sound, strongest at the apex of the heart, was readily perceived. Under local bleeding, the use of mercury, and quietude, the disease subsided, and the rubbing sound died away. The sawing sound was heard unimpaired while she remained under treatment, which she did for some months; and the heart's impulse remained greatly increased at the period of the last examination.

It is somewhat remarkable, and to me it appears worthy of notice here, that these three examples of inflammation of the heart, or of a part of it, comprise, with the exception of one or two doubtful ones, all the instances of that disease which I find recorded in my case-books for the last ten years, among some thousand cases of acute disease, including many examples of acute rheumatism. Minor and more insidious attacks may doubtless have escaped my observation, and have grown with time into greater importance, after having passed from under my inspection. It is a matter of uncertainty with me, whether I should refer one very interesting case of disease of the heart in an infant (to be related at a later period) to inflammatory action, or to a rupture or lesion of a valve or valves.

With respect to acute rheumatism, the results of my experience are certainly very encouraging. The example I have selected above is the only one which I have found complicating rheumatism, although my attention was early drawn to the risk of the combination, from having been myself a severe and repeated sufferer from the latter disease in my youth. In the case I have recorded, it is related that the patient was very ill attended to, and that she was in the habit of going out into the open air while suffering rheumatic disease. Under proper care, she had passed through as severe an attack a year before, without any implication whatever of the heart. It is simply to confinement to bed and to a comfortable room, to the avoidance of cold, and to ordinary and reasonable treatment, rather than to the peculiar efficacy of the mode of treatment adopted, that I ascribe this important result. I may, once for all, observe, that the treatment which I have adopted in acute rheumatism, has been, for the most part, the exhibition of alkaline purgatives, and calomel and opium; when the disease has been obstinately located, with pain and swelling and heat, the application of a few leeches; and when the circulation has been persistently and greatly excited, with flushed face, head-ache, and full strong pulse, in the young and middle-aged, the abstraction of a few ounces of blood from the arm. Few things, in the treatment of rheumatism, appear

[1] Medical Gazette, February 1845.

to me to be more conducive to immunity from cardiac complication, than strict and constant confinement to bed. So important do I consider this measure, that I always inform my patients that it is a remedial agency, and not merely a mode of rest. It tends, with its hot moist atmosphere, to the object in view, by conducing very effectually to a free action of the cutaneous excretories: it brings the blood, and its noxious contents, to the surface; it derives from internal organs, and when there is a constricted condition of the internal secreting surfaces, as those of the bowels, kidney, and lungs, by a sympathetic influence, it goes far, in many cases, to effect a salutary relaxation. In treating cases of scarlet fever, however mild, I invariably order confinement to bed, with the view of preventing any implication of the kidney, heart, or other organ. Were this practice universally adopted, fewer examples of dropsy and other complications would be observed. This appears, however, so obvious, that were it not that an able systematic writer, of great influence in this country, has stated that confinement to the house is all that is requisite for the more mild form of scarlet fever, the subject would not have been at all dwelt upon.

II. FUNCTIONAL DISEASES OF THE HEART.

It is not my intention to give a detailed account of the cases of functional disease of the heart which have come under my care, but to select for comment some of the more interesting points in their history, and to furnish some statistical results.

The cases of functional disease or disorder which have occurred to me may be divided into two classes: A. Those of increased action; B. Those of defective action.

A. INCREASED ACTION. Cases of this kind have been numerous.

CAUSES. The fifteenth year has been the lowest, and the sixtieth the highest age, at which simple over-action of the heart has been observed. Most patients were between the eighteenth and the thirtieth year. Females suffered more than males, in the proportion of two to one. Season appeared to have little influence in these cases; this differs from what was observed in the case of defective action. Climate was obviously operative in one example. The relaxing climate of India had induced palpitation of the heart in a young lady. Excessive reading for many hours during the day and night induced extraordinary over-action with debility. Anxiety of mind connected with business was the precursor of the attack in several instances. Fear was the exciting cause in one case. An elderly lady was affected with violent palpitation in consequence of apprehension during the late threatenings of the Chartists. Dissipation produced the disease in two instances. A young man "was out for some days" dancing and drinking without interruption. His attack lasted some weeks. A young woman unfortunately addicted to the habitual use of spirits in excess, was the subject of long continued palpitation of the heart, simulating organic disease. Excessive lactation was an exciting cause. A lady, desirous of delaying conception, nursed her child for fifteen months, and thereby induced syncope, followed by obstinate and alarming palpitation of the heart.

Antecedent and concurrent diseases. The nervous constitution was extremely active and sensitive in a large proportion of cases. One young woman was affected with chorea, combined with very partial hæmoptysis. Two patients suffered from hypochondriasis: which in one instance was combined with extreme activity of brain, denoted by rapid speech and rapid change of subject during conversation. Hæmaturia had taken place in two examples; in one the hæmorrhage occurred after a dose of turpentine, in the other under circumstances denoting some temporary disorder of the kidney. Anæmia with venous murmur was found in one example. Aortic murmur was heard in two cases.

Symptoms. These were much the same in all the examples of over-action. There were unusually rapid contractions of the heart, with inordinate beating against the ribs and sternum, shaking the entire thorax. In some cases the contractions of the auricles could be felt by the hand, and a few of the patients mentioned that unusual movements could be felt as high as the third and second ribs; which has led me to believe that in some instances the aorta and pulmonary arteries become the seat of inordinate mobility. A sense of distress was felt in the cardiac region, causing in the mind, at first, a considerable amount of alarm. In almost every case flatus distended the stomach; and in a few, a small quantity passing up into the œsophagus, sometimes by dint of exertion of the patient, was discharged, or, as frequently happened, greatly to the distress of the patient and to the impediment of the heart, it was arrested midway, and held by spasm above and below, and formed a small but tightly distended, and, as it were, solid bag of air. The amount of air generated in the stomach was in the case of some of the patients exceedingly great. One gentleman would for hours, with effort, belch up a large volume of gas every two or three minutes. The stomach and lower part of the œsophagus would thus find relief, but only for a minute, as the gas was immediately replaced by more. So great was the quantity of air thus generated and discharged, that it was somewhat difficult to understand how the contents of the stomach, small in quantity as they were, could produce so much air, even under circumstances the most favourable to fermentation. The over-activity of the heart, perhaps, by monopolising power, and leaving less at the disposal of the digesting organ, and the anxiety of mind, by a depressing influence communicated to the stomach, contributed much to this most distressing symptom. It was the remark of some, that if they could only get rid of the air in the stomach, they would soon be all right. This much has been said on this point, partly with a view to a certain mode of relief to be suggested at a later part of this communication. The pulse was almost without exception feeble, jerking, and small: rapidity was a constant feature. The pulse at the right wrist in one patient became imperceptible, on the assumption of the erect or even the sitting posture; the left was very feeble, yet was to be felt. The horizontal position was necessary, even during violent palpitation, to preserve the patient from an overwhelming sense of faintness. A sense of sinking and faintness was a frequent attendant, and a minor form of trembling seized the patient. Sometimes the face was pallid, and soon after greatly flushed. The

bowels were little affected. The urine, on the other hand, was signally modified. During paroxysms of palpitation, and immediately after, the urine was abundant or excessive, almost colourless, and of very low specific gravity. The gentleman who suffered so much with flatus passed urine showing no appreciable weight above that of pure water, at the rate of 5 oz. in ten minutes, during some hours. It had no taste, but had a slight odour resembling beef tea. It threw down phosphates freely on the addition of liquor ammoniæ. This urine would be succeeded next day by scanty, deep sherry-coloured urine, of high specific gravity, above 1·020. The urine in one example was, as it were, brilliantly illuminated by a profusion of crystals of the triple phosphate.

Physical Signs. These presented little remarkable. The sounds of the heart were short, smart, and loud; the first resembling the French "eu", and the second "up" pronounced hard. The impulse was greatly increased, sometimes succussing the whole or part of the thorax. Over the second rib and corresponding part of the sternum in the case of the gentleman who had suffered hypochondriasis and hæmaturia, a distinct humming sound, synchronous with the systole of the heart, was unequivocally made out, proceeding obviously from the aorta, probably in a state of moderate orgasm. No venous murmur was to be heard in the neck. It is a curious circumstance, and one which reflects light on that just related, that I was enabled to discover the same humming sound in the same parts in the sister of the patient. She too suffered from palpitation of the heart unconnected with organic disease. Her health, never robust, had recently suffered from nursing her infant.

The circumstances which aggravated the disease were exertion, emotion of the mind, full meals, and stimulating drinks. In more than one instance, wine and spirits proved very injurious. Bread in one case caused such an enormous quantity of flatus, as to be very hurtful.

Treatment. The treatment found most efficacious was the removal of exciting causes as much as possible, quietude, and sustaining the strength without causing excitement. Animal food in moderate quantity was found most suitable. When flatus was annoying, this was materially abated by giving the food cold, such as cold jelly, or cold beef tea, with only a small allowance of bread. The medicines most useful in obviating excessive action were hyoscyamus and hops, given alone or conjoined, in tincture or in extract. The bowels, when requiring assistance, were advantageously moved by means of the compound rhubarb pill, with or without a grain or half a grain of camphor. After the disease had subsided, benefit accrued to the general health from the use of vegetable tonics, followed at a later period by chalybeates. Under this treatment, with additions modified to meet the specialities of particular cases, all the patients did well, and none in the end gave any reason to fear the actual commencement of organic alteration.

The horizontal posture was found in more cases than one to make the patient more tolerant of the heart's excessive palpitation, and appeared to favour its subsidence. This posture, however, was sometimes eagerly exchanged for the sitting position during flatulent distress and during efforts to discharge air through the œsophagus. It appears to me that this relief from the horizontal posture was procured by

a reduction of the labour or effort required to be made by the heart, secured by the more ready passage of the blood along a horizontal, than upwards through a vertical tube.

B. Defective action. Several examples of defective action of the heart have come under my notice, but they have presented very few points of interest. The defective action was manifested in weak and fewer contractions of the heart, for the most part accompanied by a greater or less degree of faintness or sinking. The heart's contractions would occasionally cease for a few seconds, causing to the patient a sense of stoppage and fulness at the heart. The sounds of the heart were low but clear. The pulse was of good size, soft, compressible, and often intermittent. Flatus in the stomach, and pallidity of face, were common.

Causes. Fatigue was a very common cause of defective action. Anxiety of mind and sudden emotion have for some moments appeared to suspend the heart's action. Adults only suffered; the sexes in much the same proportion. The heat of summer and autumn caused the attack in several patients. In the summer of 1846, when the heat was very great, some bad cases occurred.

Treatment. Cold ammonia and spirits were found to give relief at first. This was advantageously followed by tonics. Rest from labour was found necessary; and, in some instances, great advantage followed removal into the country, and exposure to the cool breeze, when that could be secured. The horizontal posture was so serviceable, that it was almost involuntarily assumed by the sufferers.

Besides the idiopathic cases of defective action of the heart, I have found in several examples of disease of the brain and medulla spinalis, indicating softening and inaction of these parts, a very decided and very unequivocal debility of the heart. This is somewhat interesting; and I therefore shall proceed to notice one or two examples.

A young married lady consulted me about eight years ago on account of a constant tremor of the eyelids of one eye, and twitching of one angle of the mouth, together with pain at the coccyx on sitting down or on attempting to rise. Rapid and silly talking suggested a weakly brain. The general health was excellent, the face was florid, the body altogether in a state of embonpoint, but the pulse was remarkably feeble and compressible. Disease of the brain and medulla spinalis was suspected. The tremor and twitchings passed off, but reduced sensation soon after occurred, and the patient is now little above the level of an idiot, and can with difficulty stand or creep round a table. The action of the heart is exceedingly feeble; the sounds are low. The pulse ranges about sixty, and is remarkable for want of force.

A gentleman lately called to consult me for dimness of sight and headache. He was drowsy and very fat. The heart's action was remarkably feeble for such a man; and though he was evidently of a full habit, and accustomed to a full meal and little work, I on this account avoided more depletion than I believed necessary to save him from an attack of apoplexy. He improved greatly, but some months afterwards he was seized with a fit, and fell down. A great deal of brandy was

given by the attendant who was called in, and the disease was said to be something of the nature of syncope. Good living was recommended; but the fits have since recurred several times, and they are reported by the attendant in the country to be allied to epilepsy. The patient's mind is weakened, and he is unable to perform the duties of his station.

The same debility of heart's action was remarked at the very commencement of an insidious illness which terminated, some months ago, in the death of the patient in a lunatic asylum. Silence observed to his newly-married wife, and debility, were the first indications of disease. His articulation became slow and faltering. Insanity, approaching idiotcy, was soon after established. The patient was a gentleman of forty years of age, and previously in excellent health. The debility of heart and pulse continued to the last.

III. STRUCTURAL DISEASE OF THE HEART.

Forty-two examples of organic disease of the heart, of which some account is now to be given, include nearly all the cases which have come under my notice for some years. They may therefore be taken as a fair specimen of heart-disease in a physician's practice, and of what the young physician may expect to meet. With only three exceptions, all the sufferers came under my own care. Most of them remained under treatment for some time, and most of the deaths occurred under my own notice. Some of the patients are still living, and under treatment. In these instances, the present age has been given, and the duration of the disease calculated up to this time. In other examples, these points are given at the time of patients coming under treatment. The three patients, not under my treatment, were Nos. 31, 32, and 33, in the general table. No. 33 had been under the care of Dr. Budd, in King's College Hospital. He died in a private house, and I was requested to be present at the examination of the body. The particulars of the patient's symptoms, etc., were taken from the Hospital Book, by the kind permission of Dr. Budd. No. 32 was the patient of a student connected with the Northern Dispensary: I examined the heart and great vessels. The particulars, on other points, are derived from the student. No. 31 was a patient of Dr. Willis, whom I assisted at the autopsy. A considerable proportion of these cases were seen by other physicians, either before or during my attendance.

In the arrangement of my materials, I have, for greater conciseness as well as for more ready comparison, placed many points in a general table. Facts, of little importance in themselves, become of great import in relation to a number of examples of disease. Thus, to know that dissipation and exposure were noted in one fatal case is comparatively of little consequence; but that *all* the patients, of whom this was recorded, ultimately died, is a collective fact of great significance, and is practically suggestive.

Some special points of interest, in different examples, were observed, and are thought worthy of record. These, as well as some observations on the pathology and treatment of organic disease of the heart, require separate notice.

TABLE SHOWING THE AGES OF THE ENTIRE PATIENTS.

Years.	3	9	10	17	18	20	22	25	26	32	34	36	40	43	47

No. Cases.	2	1	1	1	1	1	2	2	1	1	1	1	1

This proves that organic alteration of the heart is not unfrequently met with in early life. Nine cases occurred at and under twenty years of age. Of the forty-two patients, twenty-two were males, and twenty females.

Of the forty-two cases of organic disease of the heart, seventeen terminated fatally. Of these thirteen were males, and four were females.

TABLE SHOWING THE CHARACTER OF LIFE OF 42 PATIENTS.

Character of Life.	Exposure.	Exposure and Dissipation.	Dissipation	Violent Exertions.	Viol. Exert. and Dissip.	Dissolute.	Sedentary.	Comfortable.	Destitute.
No. Cases.	8	4	2	6	1	1	1	18	1

Of the eight patients, whose lives were exposed, three suffered simply from hypertrophy; one from hypertrophy with disease of mitral valve; one from hypertrophy, with calcareous deposit in aortic and mitral valves, with great thickening of the endocardium; one from hypertrophy and dilatation; and two simply from dilatation. Three died, and five were relieved. Of the four patients, whose lives were marked by exposure and dissipation, two suffered simply from hypertrophy; one from hypertrophy, and calcareous deposit in the aortic valves; and one from hypertrophy, dilatation, and mitral valve disease. All four died. Of the two patients who come under the head of dissipation, one suffered from dilatation, and soft fatty attenuated condition of heart; the other, from hypertrophy and dilatation. Both died. Of the six patients, whose life had been marked by violent exertions, four died, and two were relieved. Aneurism of the aorta accompanied the disease of the heart in one of the examples. The patient, whose life was one of dissipation and violent exertions, was relieved. The form of his disease was hypertrophy. The dissolute patient suffered from hypertrophy, with steatomatous deposit in aorta etc. He died. The sedentary patient's affection was hypertrophy and dilatation, and it was relieved.

Of the eighteen patients, the chief characteristic of whose life was comfort, fourteen were relieved, and three died; in one case no result is found noted. The destitute patient was relieved.

From these facts it appears, that the most unfavourable circumstances in the mode of life are dissipation, and dissipation conjoined with exposure.

Symptoms. The form of the disease varied so frequently, that it is difficult to give a distinct, and, at the same time, a concise summary of it. Reference to each case is therefore recommended. The same remark and recommendation apply to the physical signs and symptoms.

The pulse, for the most part, fell greatly in force below the force of the heart's impulse. It was almost invariably very weak and intermittent in mitral valve disease. In two examples (Nos. 12 and 14), those of two girls, aged ten and eighteen years, the pulse was regular; and this was probably owing to greater natural vigour at that time of life. The intermittent and irregular pulse has been observed to become regular under unusual excitement of the circulation; and, on the other hand, the nearly regular pulse has become extremely irregular and intermittent under the increased excitement of the heart.

Antecedent Disease. Certain morbid conditions co-existed with, or occurred antecedently to, the accession of disease of the heart, as far as could be ascertained, in thirty-one of the forty-two patients. In respect to eleven, nothing was made out. Seven had suffered from rheumatism on one or more occasions; one from that disease, and distortion of the thorax; five from inflammation in the chest; two from metritis and white-leg following parturition; one from miscarriage, causing great debility; two from distortions of the thorax; one from a contusion of the chest from a kick from a horse; one from gout with deposit; one from scarlet fever; one from colica pictonum; one from laryngismus stridulus; one from fever in India; one from bad health from infancy; one from general weakness; one from gonorrhœa, with hernia humoralis; one from bad development of skeleton; one from bad development and small-pox; one from abscesses in loins; and one from rapid and great distortion of skeleton.

Rheumatism maintains its character as a frequent cause; and the exanthematous diseases exhibit the same relation, though certainly to a much smaller extent. Small-pox and scarlet-fever are found as antecedent diseases, under circumstances suggesting their operation as causes. I believe that rheumatism and some febrile diseases frequently produce disease of the heart from a culpable neglect of moderate precaution. One of the patients came to the Northern Dispensary, suffering from acute rheumatism and pericarditis, with "to and fro sound", and loud internal murmur. A little boy, who died under my care of pericarditis with sero-purulent effusion consequent upon scarlet-fever, had been carried as an out-patient to an hospital till within a few days of his death. Laryngismus stridulus evidently induced the disease in a child when only six months old. Valvular disease was discovered during his convalescence. Palpitation had been remarked occasionally, while the breath was suspended, which it often was for about a minute as completely as if the glottis had been entirely closed by the hand. It was thought at first that the valves of the pulmonary artery had been lacerated by accumulation of blood in the vessel; but the integrity of the patient's respiration, and freedom from blueness, with the extraordinary loudness of the valvular sound at the present time, three years from the

date of his illness, rather refer the lesion to the aortic valves; which probably during the disturbance of the circulation and respiration produced by the fits, which were accompanied, moreover, by severe general convulsions, became the seat of inflammatory action, ending in effusion of lymph, and in permanent alteration of the valves. Distortion of the thorax, cramping the heart and impeding its action, was obviously instrumental in the production of the disease in a few examples. Gymnastic exercises were apparently operative to the same end in the case of a young man. Metritis, with swelled leg, was antecedent in two cases; and it is not unlikely that the inflammation of the veins was propagated to the heart, and resulted in the morbid alteration which there took place. Rapid and very great distortion of the spine and thorax certainly evoked a murmur, if it did not *cause* valvular disease, and probably contributed to the alteration of the walls of the heart. "Inflammation in the chest" was antecedent in some instances; and it is very probable that the heart became implicated in the more general affection, and ultimately led to the morbid alteration observed. In a few examples no cause could be satisfactorily made out. It has often happened, in regard to disease of the heart, as well as in regard to disease generally, that I have failed to obtain an explanation of its occurrence; and it has always appeared to me more likely to advance our knowledge to confess this, than, on slight and fallacious grounds, to adopt this or that as its ascertained cause.

Classification of the Cases. The forty-two cases of organic disease of the heart, which have been tabulated, present many points for comparison, each of which might serve as the basis of classification. But, as this is a practical communication, the point which I have selected as the ground of division of these cases, is one of obvious practical utility, viz., the limitation of the disease to the heart itself, or the implication of other organs, as indicated by the destruction of the general health, the occurrence of dropsy, of reiterated hæmorrhage, or other grave contingencies. This classification will, in fact, be one, first, of twenty cases, confined, as far as has yet been ascertained from their history, to the heart itself; and, secondly, of twenty-two with grave and probably incurable complications of distant organs. Perhaps it would not be inaccurate to say, that while the one group has attained the length of the second stage, the other has proceeded no farther than the first.

In practice, such an arrangement of examples of diseases of the heart, though it boasts nothing whatever of the distinctions of morbid anatomy, and demands no nice power of minute diagnosis, attainable only by long practice, is, nevertheless, calculated to subserve the great end of medical science, perhaps more than any other. It is not my object to disparage the divisions founded on the nature of the morbid alterations, or on the localisation of the disease. Such divisions as those of hypertrophy, of dilatation, and valvular obstruction, are doubtless of vast interest and importance; but they are so much more in a pathological than in a therapeutic point of view.

That the division I have here made is superior, for the direction of the treatment, to that founded on the nature of the morbid alteration, will appear from a reference to the cases. The morbid changes usu-

ally made the grounds of division, are found almost equally in the two groups of cases. Thus we find hypertrophy alike in the very formidable and in the merely local examples. We find valvular disease with abnormal sounds, in several examples of mere local disease, though of long duration, as well as in the cases involving serious complications in other parts of the body.

To know that the heart is enlarged, and that its walls are thickened or attenuated, is doubtless important and interesting; but, if the physician makes this the chief object of his search, and believes that, in diagnosing correctly between thickening and thinning, he has made out the most important facts of the case, he is greatly deceived, and in practice he will assuredly fail to be as useful as he might be. These conditions, in themselves, afford very indifferent guides in practice; and, indeed, are to be found in examples of disease requiring greatly diversified treatment. I believe that, in thus commenting upon this classification, I may be useful to the student and young physician, by inducing them to regard, at least in practice, rather the broad and obvious requirements of disease, as known by its limitation to the heart, or by its distant implications, than the nature or extent of the morbid alteration in the thickness of the heart's walls,—important though that be, particularly in a pathological point of view.

This classification is, like every other, embarrassed with its drawbacks. The case which is to day complicated with hæmorrhage, or, it may be, dropsy, may, ere long, under judicious treatment, be deprived of these adjuncts; and the disease, limited at present to the heart, may ere long involve distant organs. Still, though the arrangement of the case must be changed, we have the guides for treatment.

The presence of *valvular disease* forms a good pathological ground for classification. It is, for the most part, readily detected by the presence of abnormal sounds. Of the forty-two cases, thirteen gave evidence of valvular disease by abnormal bruits. Abnormal sounds were heard in six of the local examples, viz., cases 1, 11, 12, 13, 14, and 16; and in seven of the cases accompanied with complications, viz., cases 22, 23, 26, 31, 33, 35, and 37. But valvular disease is a sign of little value, both in respect of treatment and prognosis. We find it alike in the slightest and the most severe and advanced examples of disease; and the auscultatory signs of its presence are not always to be heard. Valvular sounds, which had at an early period been well made out, would at a later period become altogether, or for a time, inaudible. This probably arose from reduced force of the heart's action no longer being sufficient to propel the blood with sufficient force, and not by any means, as the over-sanguine might conclude, from the removal of the obstructing parts under the influence of treatment. The intensity of the valvular murmur did not always correspond with the amount of disease of the heart, or with the importance of the valvular alteration. The vigour of the heart's action, as well as youth and good general health, seemed to contribute largely to the intensity: the sounds in the limited or local examples were of the loudest. On the other hand, valvular disease, of great importance, connected with very great alteration of the heart, was present in one example, without any murmur having been heard at any time, though diligently sought for.

Any grouping of the cases on the basis of the thickness of the walls

of the heart, will here prove of very little value; the alteration in this particular being much the same in examples requiring very different treatment.

An important division of cases of organic alteration of the heart would be one founded on the healthy firm character, or the disorganized, soft, broken-down alteration of the walls of the heart. But, in practice, it is difficult to diagnose these conditions by physical signs, and we are compelled to have recourse to symptoms, and the general condition of the body. Now, for the most part, the healthy firm heart is found only in the more limited cases, and the disorganized heart is seen only in the complicated examples; so that the division first noticed in this paper will practically be also one of,—first, firm and vigorous structure; and second, of disorganised, soft, inefficient tissue, this being, in my opinion, the most formidable and important alteration, and the prevention and arrest of which is a main indication. So very generally is the heart found firm, or moderately firm, and vigorous, in those examples of disease which still remain free from general breaking up of the health, hæmorrhage, and dropsy, and so commonly is the heart found softened and disorganised in its muscular parts, in those cases marked by these grave contingencies, that I am disposed, in a general way, to regard the first condition as the first stage, and the second condition as the second stage of the same disease; using the word *disease* in a wide and comprehensive sense, and acknowledging it to display manifold varieties, as well as to possess a certain unity of character.

A. Local Cases. The ages of the patients, whose disease was chiefly local, are arranged in the following table in quinquennial periods.

Ages.	0 to 5	5 to 10	10 to 15	15 to 20	20 to 25	25 to 30	30 to 35	35 to 40	40 to 45	45 to 50	50 to 55	55 to 60	60 to 65	65 to 70	70 to 75	80
No. of Cases.	1	3	0	4	2	3	1	1	2	0	0	0	1	0	1	1

The average age of the patients is about thirty years. With regard to the sexes, eleven were females, and nine were males. The greater proportion of females, in this list, may possibly be explained on the supposition that the greater care they take of their health, their more protected mode of life, and their greater freedom from hard labour and dissipation, contributed greatly to arrest the development of disease beyond the primarily suffering organ. The duration of the disease varied from two months to twenty years; and as the period could not be accurately determined in some cases, it may have lasted even longer. This shews, that organic disease of the heart may not only permit the patient to survive many years, but that without hæmorrhage, dropsy, or permanent damage to the general health; in short, with very limited suffering. The observations of Dr. C. J. B. Williams (London Journal of Medicine, April and May 1850) and Dr. R. H. Semple (*Ibid.* November 1850) tend to shew that heart-disease is, in itself, not so incompatible with long life as is often supposed. The interesting cases, recorded by the latter gentleman, prove still more:

they shew that patients may attain old age, with a considerable degree of comfort, even with long-standing apparently formidable valvular disease.

The form of alteration of the walls of the heart, in ten examples, was hypertrophy; in ten, it was hypertrophy combined with dilatation. Of this group of twenty cases, six were marked by abnormal valvular sounds.

The results of these cases were exceedingly satisfactory. Relief was afforded in every case. In some the benefit was great, and promised to be lasting. Death occurred in one example only, that of an octogenarian; and this proceeded more from great and rapid distortion of the body, than from disease of the heart.

B. Complicated Cases. The ages of the patients whose disease extended beyond the primarily affected organ, whose general health was materially injured, and who suffered from dropsy or hæmorrhage, may be classified as under, in quinquennial periods.

Ages.	15 to 20	20 to 25	25 to 30	30 to 35	35 to 40	40 to 45	45 to 50	50 to 55	55 to 60	60 to 65	65 to 70	70 to 75
No. of Cases.	1	0	0	1	6	0	4	1	3	4	0	2

The average age was about fifty years. This is much higher than the average age of the patients suffering only from local disease, viz., thirty years; and is what might have been anticipated, because the progress of years is calculated to convert local into general and complicated disease, and because disease of the heart, at an advanced age, is likely to meet with less resistance than in comparative youth, when the powers of life are yet abundant, and the tissues are firmer, and possessed of more elasticity.

Of the twenty-two patients suffering from hæmorrhage, or dropsy, or both, thirteen were males, and nine were females. Thus males suffered more than females, which is the reverse of what was observed in respect to merely local disease; eleven females, and nine males, making up the number of patients more lightly afflicted.

TABLE SHEWING DURATION OF COMPLICATED CASES.

Duration.	Some Months.	2 Yrs.	3 Yrs.	7 Yrs.	8 Yrs.	20 Yrs.	27 Yrs.	40 Yrs.	Some Years.	Many Years.
No. Cases.	3	1	3	1	1	1	1	1	6	4

The duration of each case, with the exception of a few still under treatment, is given only up to the time when it first came under my notice. Some of the patients lived for some years after. Care was taken to obtain the most correct information on this as on every other point; and it may be regarded, if not as absolutely precise, still as a very near approach to it. With respect to the instances of long duration, viz., twenty, twenty-seven, and forty years, there is no doubt whatever of the accuracy of the information. The patients were all intelligent and trustworthy men. One was the father of a medical friend, not likely to be deceived; and his testimony was corroborated

by examination after death. The gentleman, who had been ill forty years, was a particularly intelligent Scotchman, till within a few months of his death serving with his regiment in the West Indies. He distinctly assured me that he had suffered from disease of the heart for forty years, and that the extraordinary palpitation, which I have endeavoured to describe, was wont to attack him during the whole of that long series of years.

The form of alteration of the walls of the heart, in the twenty-two complicated cases, is seen in the subjoined table.

Alteration.	Hypertrophy.	Dilatation.	Hypert. & Dilat.	Uncertain.
No. Cases.	11	3	7	1

In seven of the twenty-two cases, valvular or abnormal bruits were made out. This is rather more frequent than in the more limited cases; in only six of which were abnormal sounds heard. The results, as might be anticipated, were, in this group of cases, greatly less satisfactory than in the other. Sixteen of the cases terminated fatally: six of the patients were relieved.

Concurrent Diseases. Congestion was the first implication of other organs; and in the examples before us it was, almost without exception, passive. The head was congested in some instances, from the obstructed venous circulation. In only one or two was the congestion at all of an active character, and then it arose more from the agitated condition of the body, and the impurity of the blood, than from any undue violence with which the diseased heart discharged the current of blood. A very anæmic condition of the system did not prevent a patient (No. 36) from suffering much from this complication.

Congestion of the kidney has obviously been instrumental in the production of dropsy. It has destroyed the tone of the organ, and ultimately so injured its vitality as greatly to interfere with its due secretion. This has received much countenance, from the urine becoming more abundant when hæmorrhage has taken place.

Of the forty-two patients, eighteen suffered from head affections, embracing various forms of disease, including active and passive congestion, convulsions, coma, delirium, and headache.

Twenty patients were affected with disease of the lungs and bronchi. Ten suffered from congestion of lungs; one from congestion of bronchi; one from emphysema and black, old tubercles; one from emphysema and chronic bronchitis; two from chronic bronchitis; one from œdema; one from hepatization; one from probable œdema; one from displacement of lung by enlarged liver; one from tubercles and cavities; one from tubercles; one from emphysema, œdema, congestion, and chronic bronchitis.

Of the twenty-two patients, thirteen suffered from hæmorrhage in one form or another. Eight suffered from hæmoptysis, one from hæmoptysis, hæmatemesis and melæna, two from melæna, one from hæmorrhage from bowels, and one from hæmorrhage from bowels and hæmoptysis. In case No. 21, it was remarked that the urine was albuminous until melæna occurred, when the albumen disappeared from the urine; but as soon as the melæna ceased, the urine again became albuminous.

Spontaneous hæmorrhage has afforded great and immediate, if not very lasting benefit to some of the patients. It has done this by relieving congestion, and thus withdrawing one of the obstacles to free secretion. This has been observed even when the blood has been scanty, or highly diluted. Perhaps the benefit from this natural or spontaneous bleeding may not be without a wholesome suggestion to those who, ever eager to adopt every novel doctrine, though opposed to the well tested experience of ages, on all occasions, to the detriment of the sick, and to the injury of a noble calling, repudiate the assistance of the now too much disparaged lancet.

TABLE SHOWING THE RELATIONS OF DROPSY WITH HÆMORRHAGE, ETC.

No. as in general able.	Dropsy.	Hæmorrhage.	Liver.	Kidneys.	Result.
21	Œdema of feet.	Hæmoptysis, hæmatem., melæna.	No disease.	Kidneys only rather small, albuminuria.	Death.
22	Ascites, œdema of feet.	None.	Great hydatid tumour.	No disease.	Death.
23	Ascites, anasarca of legs.	None.	Enlargement.	No disease.	Death.
24	Œdema of feet.	Hæmoptysis.	No disease.	No disease.	Relief.
25	Anasarca of legs.	Melæna.	No disease.	No disease.	Death.
26	Ascites to great extent; anasarca of legs & hands.	None.	Cirrhose.	No disease.	Death.
27	None.	Melæna.	No disease.	No disease.	Relieved.
28	None.	Slight hæmoptysis.	No disease.	No disease.	Relieved.
29	Ascites to great extent, hydrothorax, hydropericardium, œdema of lungs; anasarca of legs.	None.	Cirrhose.	No disease.	Death.
30	Great anas. of legs; œd. of lungs.	Hæmorrhage from bowels.	No disease made out.	No disease made out.	Death.
31	Hydrothorax, ascites, anas. legs.	None.	Cirrhose to great extent.	No disease.	Death.
32	None.	None.	Cirrhose.	Bright's disease in first stage.	Death.
33	Œdema of face.	Hæmoptysis, aneu. of aorta.	No disease.	No disease.	Death.
34	Ascites, œdema of feet.	None.	No disease made out.	No disease.	Relief.
35	Hydrothorax, ascites.	None.	Diseased.	No disease recorded.	Death.
36	Ascites, anasarca general.	From bowels, hæmoptysis.	Great enlargement.	No disease.	Death.
37	Anasarca, great.	None.	No disease.	No disease made out, albuminu. 2 or 3 occasions.	Death.
38	None.	Hæmoptysis.	No disease.	No disease.	Much rel.
39	Hydrothorax, anasarca of legs.	None.	Congestion.	Cyst containing tubercular matt.	Death.
40	None.	Hæmoptysis.	None made out	No disease.	Relieved.
41	Hydrothorax, anasarca of legs.	None.	No disease.	No disease.	Death.
42	Œdema of feet.	None.	No disease.	No disease.	Death.

Dropsy was intimately connected with the soft, flabby, inefficient, disorganised heart. There was reason to believe that dropsy was the effect; but there is ground also to believe that the general effusion of serous fluid into the tissues again materially aided the further progress of the disorganisation of the heart.

Of the twenty-two patients in the second division of the table, seventeen suffered from dropsy in one form or another; three from œdema of the feet;[1] two from œdema of feet and ascites; one from ascites and anasarca of legs; two from anasarca of legs; one from ascites and anasarca of hands and legs; one from anasarca of legs, ascites, hydrothorax, and hydropericardium; one from anasarca of legs, hydrothorax, and ascites; one from œdema of face; one from hydrothorax and ascites; one from ascites and anasarca; one from anasarca; and two from hydrothorax and anasarca of legs.

From the above table it appears that out of seventeen cases in which dropsy occurred, fifteen terminated fatally. In some cases, the amount of dropsy was slight, and the effusion was confined to a part. In others, the amount was great, and different parts formed its seats. In five cases, hydrothorax occurred; in one, hydropericardium. The effusion was confined to the face in the case conjoined with aneurism of the ascending aorta. Ascites took place in eight cases; and it is remarkable that in six of them there was found organic disease of the liver. While this teaches that ascites may be looked for more frequently where there is organic disease of the liver, it also suggests the practical precaution, when ascites occurs, of looking beyond the liver, and of ascertaining the condition of the heart.

Besides the facts given in the tables, there are a few connected with these cases which are too important to be altogether passed over.

One of the first facts of importance which suggests itself to my mind, is the frequency in which I found that disease of the heart had not been made out until a very late period, in some examples only a very short time before death, although there was good ground to believe that the disease had been of considerable duration. In some instances, this has arisen from inattention to obvious evidence; in others, from the absence of some of the more common indications, such as palpitation, pain or oppression, particularly in the region of the heart, or from the impulse and sounds of the heart being in some measure obscured by effusion in the lung or pleura, or by emphysema. In some examples, it is not unlikely that it arose from a current but fallacious idea that there must necessarily be heard, in organic disease, abnormal bruits and marked alteration of the sounds of the heart; and that when these are not made out, symptoms alone, such as palpitation, blue face, dyspnœa, dilated veins, etc., are to go for little or nothing. One gentleman (No. 39 in the general table) had the sounds and impulse of heart so masked by emphysema and œdema of the lungs, together with much flatus in the stomach, that his disease, great as it was, was not made out by two of the oldest physicians in town, who had attended within a short time of his death. The feeling of the patient in respect to the stomach being the chief seat of disorder, may

[1] One case of slight recent œdema of the feet in a patient aged 80, remains in the first table.

likewise be operative in leading to this error. A patient (No. 37 in the general table) spoke so confidently of his disease being merely "wind in the stomach", that I felt it my duty to inform him that it was much more serious; but he apparently treated my information on this point as unworthy of consideration.

The anæmic venous murmur in the neck, which had been distinctly heard in case No. 36, before the jugular veins became greatly dilated, and the seat of regurgitation, on the occurrence of these conditions was no longer heard, although the blood continued fully as much diluted. This cessation was probably due to the subtraction of one of the necessary conditions for the production of the sound; viz., a certain amount of rapidity of current.

Diagnosis. The diagnosis in advanced organic disease is, for the most part, sufficiently easy; though, as we have seen, even great alteration may be marked by emphysema, œdema, or flatus. A careful examination of the impulse and the sounds, of the patient's narrative, and of his general condition, will leave little room for doubt. But it is otherwise in the commencement of those examples of disease, unproclaimed by valvular murmur, or by recent acute inflammation, and attended by no very obvious alteration of the impulse, sounds and rhythm of the heart, alteration in the colour of the blood, or dyspnœa, not referrible to disease of the lungs and bronchi themselves. The difficulty is indeed great, in such cases, to decide at one examination of the patient at the physician's house. I have generally found the heart, when only functionally affected, to be very agitated on the first visit of the patient, and to convey to the hand the feeling of an enlarged organ. It is well, under such circumstances, not to proceed at once to the examination, but cheerfully to divert the patient's mind, and to have a second, or even a third examination. If we still find the impulse beyond its normal force and boundaries, we are scarcely warranted in allowing humanity, or a regard for the patient's feelings, to lead us to assure him that there is no disease. Whenever disease, though moderate, has been diagnosed, I have deemed it my duty to inform the patient of it. A contrary course would have compromised his interest, by interfering with suitable and persistent treatment; and the risk of evil from apprehension has been avoided, by explaining that disease of the heart is manageable; that it is, for the most part, contrary to general opinion, not remarkable for its rapidity of course, or for the suddenness of its termination. After all, it is often more a matter of curiosity than of real importance to the patient, to decide whether the heart is or is not what is usually called organically altered; for we find the worst consequences, such as venous congestion, dropsy, and death itself, following very moderate change; while, on the other hand, persons have lived for many years with great alteration, both of valves and walls, without heart-disease having been even suspected, and have ultimately died of other affections, to reveal after death, for the first time, the true condition of the great central organ.[1] If there is, how-

[1] For an illustration of this fact, see Dr. Semple's paper on Diseases of the Heart, in the London Journal of Medicine for November 1850.

ever, one condition that it is important to diagnose, it is the soft flabby inefficient heart: that is, of all other changes, the most important; and it signifies little whether or not it be conjoined with enlargement or valvular alteration. In this form of disease, the sounds are weak, and the pulse intermittent, irregular, and feeble. But the blue or pallid countenance, the continuous dyspnœa, the tendency to œdema, the general debility, and the softness and weakness of the voluntary muscles, will greatly assist the diagnosis. Amongst the first symptoms of disease of the heart I have found a moderate amount of pretty constant dyspnœa, with a sense of stoppage at the left nipple, followed by a knock. These symptoms have led, in some instances, to the diagnosis of heart-disease formerly unsuspected.

Prognosis. The prognosis, judging from the cases given in this paper, may be favourable when there is no very great narrowing of the outlets, when the heart is still possessed of tone, and when the patient is young and in fair general health, and when the disease is confined to the heart. Youth enables the suffering organ, for the most part, to maintain a suitable balance between increased obstruction to the propulsion of the blood, and the increased force demanded. The heart becomes larger and more powerful in its contractions. The prognosis is unfavourable when there is great obstruction or inefficiency of valve, permitting regurgitation into the veins, when passive congestion takes place in the viscera, and dropsy manifests itself. When the heart has become soft and flabby with very inefficient action, especially if conjoined with anæmia, there remains little or no prospect of lasting improvement. Persistent dropsy and repeated hæmorrhage argue a fatal termination. Old age and enfeebled health afford little resistance to the increased difficulties of the circulation. If the heart becomes larger, it is chiefly by dilatation and mechanical extension, aided by a soft expansile and atonic muscular structure, and marked by false movements, alike unfavourable to the currents of blood to the heart, and to the discharge of blood from it.

Treatment. In the treatment of those examples in the disease which was confined to the heart, the indications which were kept in view, were:—1st. The abatement of inflammatory action, even in the most mitigated forms, by the application of leeches, counter-irritation, and the usual measures. 2nd. The abatement of inordinate action, by the use of harmless sedatives, such as hyoscyamus, and conium, or lactucarium. When the action was great, and attended with pain, morphia was administered. When quieting was required at the same time that a tonic was admissible, hop was administered with great advantage: it was usual to continue its use for weeks, often in combination with a bitter infusion. When vigour was wanted, and there was no extreme irritability, iron was found to afford lasting advantage.

In the treatment of the more serious cases, those complicated with congestion, hæmorrhage, dropsy, etc., the objects of the treatment were more numerous.

A heart organically altered is not incapable of inflammatory action. It was therefore necessary, on some occasions, to adopt measures against this evil. But great care was taken not unnecessarily to tax the powers of the system.

When congestion occurred, the treatment consisted in gently soliciting the secretions of the part affected, if a secreting organ; if the head or lungs were affected, a few leeches, or the cupping glasses, were applied in the neighbourhood; and when circumstances would admit, mild purgatives were employed. The congestion of the brain, in one example, was so great in consequence of regurgitation, that, though the patient was anæmic, it was deemed necessary, in order to save him from an attack of apoplexy, to open a vein in the arm, and draw two or three ounces of blood. The result was satisfactory. The patient was immediately relieved from severe pain, and an almost delirious state; and no obvious increase of debility followed.

In these examples very violent palpitation occasionally occurs, causing pain, dyspnœa, and extreme anxiety. The stronger sedatives, such as morphia, are then demanded. The effect of morphia, under such circumstances, has been most gratifying; a quivering heart, with rapid and extremely small and irregular pulse, has within an hour been changed into a comparatively quiet and efficient organ, with a soft, full formed, calm pulse. Under such quieting treatment I have known even very marked regurgitation of the jugular veins to disappear; the venous blood finding a more ready passage through a better working engine. For constant use, to prevent inordinate over-action, the tincture of hop has proved of inestimable value.

Dropsy demanded much attention. When it depended on congestion from direct heart obstruction, the saline purgatives and diuretics were administered. When a slight stimulus was admissible, the spirit of nitrous ether was added. These means, for the most part, gave some relief. When dropsy depended on debility, as it did in some examples towards their fatal termination, the evil was met by the use of spirits of ether, in a little infusion of broom tea and squills, supported by the moderate employment of Hollands.

In those examples of dropsy dependent on visceral congestion, as not a few were, an attempt was made to remove this secondary condition. When the liver was obstructed, a few leeches were applied over it, and mercurials administered according to the resources of the patient. When the kidney was congested, little good followed the use of diuretics. When all other means failed to relieve pressing dropsical swelling, recourse was had to the formation of an artificial outlet in two cases, and with manifest advantage. One of these cases was ascites; the other, general anasarca. No evil whatever resulted. In the case of anasarca, small incisions were made along the legs, and the fluid trickled out for days, until the whole dropsical effusion was got rid of, much to the comfort of the patient. The adjoining integument was besmeared with some simple ointment, and the leg was enveloped in dry, soft, chamois leather, which imbibed the fluid as it escaped, and formed a bland warm application to the limb; a happy exchange for hard irritating linen cloths.

In dropsical effusion, extraordinary benefit has been observed to follow the use of mercury in some of these examples, as well as in other cases. When œdema of lungs has threatened, a few grains of blue pill, combined with squills, have afforded great relief to the respiration and much increased the flow of urine. When the whole catalogue of diu-

retics had in vain been tried, and scarcely an ounce of urine would be passed in twenty-four hours, with increasing effusion in the different cavities and in the cellular tissue, it has appeared desirable to restore the urinary secretion, even at some cost to the patient. Mercury under these circumstances has been administered, but with varied results. One circumstance commonly noticed has been the difficulty of affecting the gums; extraordinary quantities of mercury have been given before the slightest effect has been produced upon those parts. The difficulty has been, for the most part, proportioned to the obstruction of the circulation and the debility of the patient. When the gums have been at last affected with the red mercurial line, and the health has become slightly touched, then the urinary secretion has, in some instances, been surprisingly and suddenly rendered abundant. In example No. 36, in which anæmia existed, the gums, notwithstanding the long and free use of calomel and blue pill, remained pale and like white wax. At length a faint red line fringed the gums; this was the signal for the urine to flow in almost incredible amount. One day, I left the patient to pay a visit to Boulogne; he was then an enormously swollen man, lying very ill in bed. In three days I returned; he met me in the lobby, a thin and emaciated person; so great was the change, that I jocularly inquired of him how my patient up-stairs was going on, affecting not to recognise him. The gums had become tender, the mercury had told in some extraordinary way upon the effusion, and in three days had totally removed it, although every variety of diuretic and every contrivance had been employed for this object, for weeks, in vain. After a lapse of some considerable time, the dropsy and suppressed urine returned, but again to be removed by mercury. Dropsy finally established itself again, and the patient died in the country thoroughly exhausted. Did the mercury primarily act upon the kidney? did it excite the absorbents to increased activity? did it so act upon the heart as to cause it to operate with more efficiency upon the mass of blood and urge it along more readily in its hitherto reluctant and retarded course, unloading the distended and inactive veins, and filling the empty arteries, so as to supply an increased pabulum to the secreting organs whence the secretions might be withdrawn? or did it for a time mitigate visceral obstructions? In one way or another, it appeared that the pabulum supplied to the kidneys, in common with other organs, was increased at this time, for the pulse was decidedly larger than before.

The stomach presented some disorders for rectification. Irritability and vomiting required treatment. When the ordinary means failed, recourse was had to the use of ices, with extraordinary benefit. Iced mint tea was very grateful, and contributed to abate vomiting. Flatus proved the source of great distress to several patients. Various carminatives were employed, but with very partial and varied success. Purgatives afforded most relief. The examination of the body of No. 39 revealed such an enormously distended stomach, as fully to explain the great sufferings of the patient from flatulence. When the walls of the abdomen were divided, the stomach rose up in bold relief, an enormous bag of air, far above the other organs. It occurred to me, on reflecting on this condition of the stomach, and the great distress it caused the

patient, who always maintained "it was only his stomach", that it would have afforded the sufferer great relief if a narrow elastic tube had been passed down the œsophagus, and had given vent to the pent-up gas.

I believe that such an instrument might under similar circumstances give great, though possibly only temporary relief. For a time, at least, it would comfort the patient, and give the heart more room to act. It is not impossible, moreover, that more than temporary advantages might result from it. Relieved from continued distension, the stomach might regain some of its long-lost tone, and less readily permit the evolution of gas, and more willingly contract upon it and cause its expulsion. I had lately an opportunity of observing how relief from long-continued distension of an organ will restore its tone and contractility. A gentleman, aged 40, consulted me for incontinence of urine of many years' duration. It had caused him and his family very great annoyance. I introduced a catheter into the bladder, more for the purpose of exploring the urethra than of emptying that organ; a large quantity of urine came away. Next time I saw him, he was extremely delighted to inform me, that ever since I had passed the catheter, he had made water as well as he had ever done in his life, instead of his urine constantly dribbling away from him. Instead of incontinence, he had distension; and the temporary relief afforded by the catheter, led to a complete cure. It is not too much to hope, that some similar advantage might follow the discharge of the long pent-up air in a distended stomach. Mr. Coxeter of Grafton-street has supplied me with an instrument, but I have not yet had the opportunity of testing its value in practice.

It is a highly important indication to retain the heart in a state of good muscular tone; and where this has given way to weakness and atony, to restore it as far as it is practicable. To retain the vigour of the heart is chiefly an object in cases of disease uncomplicated with secondary disease; for where these have occurred, the heart is, for the most part, found to be already greatly reduced in strength and efficiency. The means of effecting this object, in the more local examples, has been already noticed. If judiciously employed, they may prevent the accession altogether of the more advanced stage, or, at least, abate its progress. Fortunately we have means within our reach by which the advancement of softening and relaxation, when already begun, may be controlled; and even, under favourable circumstances, to a certain extent corrected. Amongst the foremost of these means may be ranked a sound liberal diet, comprising a large proportion of red fresh animal food, with, where circumstances connected with the health and constitution of the patient will permit, a little sound light wine; pure air; moderate exercise and driving; vegetable and mineral tonics, including sulphuric and nitric acids; and above all such tonics, for continuous use, particularly where anæmia is present, and there is freedom from irritability of the stomach, the various preparations of iron recommended in my work on its beneficial employment in such cases. One other great means of equalising the demand made upon the heart and its ability, besides doing what we can to strengthen that organ, is to relieve it as far as possible of its labour. The adoption of the recumbent or semi-recumbent posture for half

an hour, two or three times in the course of the day, will go far to prevent the still somewhat vigorous organ becoming flaccid, and give the flaccid organ a period of comparative rest, and an opportunity to recruit itself. I have reason to know that this practice has proved of essential service, and, for the most part, it is not ungrateful to the patient. Cold sponging proves of great service in this direction, and even cold bathing, in some cases, I believe would prove highly beneficial: but care would be required in the selection of examples adapted for its employment.

A course of moderate counter-irritation, at the region of the heart, has proved of great service. It has certainly kept pain in check; and has appeared to regulate action, and retard the progress of morbid growth. It is well effected by means of chamois leather dipped in linimentum ammoniæ.

TABULAR VIEW OF FORTY-TWO CASES

A. TWEN

No.	Name.	Age and Sex.	Habits of Life.	Family Disease.	Antecedent Diseases.	Duration of Disease.	Form of Dis
1	M. C.	10, F.	Comfortable.	None recorded.	Acute rheumatism, twice, treated without loss of blood.	Three months.	Hypertro with mit valve alte tion.
2	M. L.	61, F.	Exposure.	None.	Weakness and chronic bronchitis for years.	Probably some years.	Dilatatio
3	T. C.	26, M.	Habitual excess in spirits; violent exertions; shaking the person in twisting hair.	None.	Gonorrhœa five years ago, followed by hernia humoralis, leaving to this time swelling of testes.	Two years; but aggravation two last mths.	Hypertro
4	M. S.	25, F.	Quiet; comfortable.	Father died of ossified. heart, aged 70.	"Frequent attacks of infl. in lt. side of chest," treated with leeches and blisters.	Two years.	Hypertro and dilatat
5	J. C.	26, M.	Comfortable.	None.	Acute rheumatism in joints and muscles, six years ago; not tr. for a week, then removed to hosp., where had leeches appld. to region of heart.	Six years.	Hypertro and dilatat
6	B.	72, F.	Expos. to cold, wet, and steam.	None.	Gout, with deposit in hands, during last 14 years.	Ten years.	Dilatation hypertro
7	J. J.	9, M.	Quiet; comfortable.	None recorded.	Scarlet fever immediately before, during wh. pleurisy, leaving slight hepatisation of left lung.	Some weeks.	Modera hypertro

In conclusion I shall add, that the treatment to be as successful as it should be, the nature of each case must be made out, the broad indications recognized, and the most efficient and simple means of fulfilling them suitably employed. With this rule reduced to practice, the formalities of routine may be dispensed with. The necessarily limited character of a communication of this kind prevents my alluding to many topics of great therapeutic interest which I otherwise should gladly have touched upon. The same want of space has reluctantly prevented my referring to the valuable contributions, on the same subject, made by many eminent members of the profession. In further apology for this omission, I have to remind my readers that I have not aimed at the higher office of writing a treatise, but simply proposed to occupy the humbler field of relating some of my own observations.

Park Street, Grosvenor Square, March 1851.

UCTURAL DISEASE OF THE HEART.

LE CASES.

hysical Signs.	Symptoms.	Treatment.	Effects of Treatment.	Result.
pulse much in-ed, fremisse-cataire, loud lic murmur.	Much palpitation.	Not recorded.	Not recorded.	Not recorded.
unds loud, situs eart increased; 's contractions , disturbed; p. intermittent.	Palpitation, moderate dyspnœa; occasional pain in head.	Hyoscy. for dyspnœa & palpit., pil. rhei c. to regulate bowels, lin. terebin. for bronchitis.	Improved considerably.	Improved.
usual succussion ecordial region, lse greatly in-ed, situs in-ed; first sound g and rough.	Great palpitation, faint feeling at heart; moderate dyspnœa; p. weak, small, compressible; dyspepsia and flatus.	For recent aggrava., six leeches to præcardia, digit. hyoscy., sulp. magnesiæ, leeches repeated, Plummer's pill.	Was greatly relieved of urgent symptoms.	Relieved.
emor of ribs, impulse, situs increased, ds strong.	Violent palpitation, dyspnœa; p. small, firm, intermittent.	At first leeches to præcordia, digitalis intern., subseq. prep. of iron.	No benefit followed the applicat. of leeches and the administration of digitalis; gen. health was much imprvd., and palpit. reduced by iron.	Health improved and local symptoms mitigated.
embling of ribs, increased, apex at seventh rib; lse increased, as if heart were ually hard.	Palpita.; weak small pulse.	Rhubarb and magnesia, subseq. chalybeates.	Not recorded.	Not recorded.
tus of heart in-ed, impulse in-ed; sounds loud; ed veins in neck.	Palpitation, dyspnœa, cough, weak pulse.	Vegetable tonics, spir. of nit. ether.	General health improved, and local symptoms relieved.	Relief.
tus and impulse erately increas-eins of neck di-; præcordial re-more prominent corresponding of opposite side.	Palpitation; p. regular, weaker at right wrist than at left; moderate lividity of face.	Hydrarg. c. cretâ, carb. sodæ, hyoscy. first few days, subseq. iodide of iron.	Secretions improved and palpitation abated under first part of treatment; general health greatly restored by the latter portion.	Much relieved.

No.	Name.	Age and Sex.	Habits of Life.	Family Disease.	Antecedent Diseases.	Duration of Disease.	Form of Dise
8	M.	43, F.	Comfortable.	—	Rheumatism 17 years ago; injury of the right foot 12 yrs. ago; hence considerable lateral distortion of spine, raising right shoulder 3 inches above left.	Eleven years.	Hypertrop
9	S.	32, F.	Comfortable.	Rickets, small development.	Inflammation in chest when 8 years old. Bony fabric has been ill developed.	Fifteen years.	Hypertrop and dilatat to a moder extent.
10	W.	36, F.	Sedentary.	Rickets.	Bony fabric ill developed, short and contracted. Slight distortion of cervical spine in early childhood.	From childhood.	Hypertrop and dilatati
11	R. L.	18, M.	Violent exertions; temperate.	—	None.	Some years.	Hypertrop dilat., ao valvular ease, and a tic aneuris
12	S. S.	10, F.	Comfortable.	—	Acute rheumatism a year ago; a second attack 2 months ago, during which heart became implicated; ill attended to, and permitted to go out of doors; no bleeding till heart implicated.	Two months.	Mitral va disease; m derate hyp trophy.
13	H. M.	3½, M.	Comfortable.	Parents highly nervous.	Spasmodic croup, very severe, and continuing some weeks, causing convulsions for some days. Disease induced by feeding, occurred 4 months before heart disease discovered. Influenza during croup.	Three years.	Disease valves; mo rate hyp trophy.

Physical Signs.	Symptoms.	Treatment.	Effects of Treatment.	Result.
npulse increased rce and in situs, ds dull. Heart laced to right of num by distor- of spine, and raction of left of thorax.	Much palpitation for years, constant dyspn.; weakness; small pulse, 100; flatus.	Rhub. and soda to improve secretions, vegetable tonics, foll. by iron.	Health improved much; the benefit from the use of iron was very marked; the palpitation was nearly removed, and the increased impulse was greatly abated.	Much relieved.
npulse of heart tantly increased, ntly in force, tly in extent. nds rather dull, lar veins dilated.	Palpitation, violent and frequent; pulse weak, intermitt.; slight congestion of head; headache.	Iron.	Patient gained much strength from use of iron; health was greatly improved during some years from commencement of treatment, and was the same when patient was last seen.	Relieved.
itus of heart in- sed, impulse in- sed in force. Ju- r veins dilated; rmittent action.	Palpitation, intermittent pulse, dyspnœa; moderate debility; oppression in head; much flatus.	Leeches over ht. to reduce suspected congestive action, hyoscy. intern., and cataplasm of morphia to præcordia for same purpose, purgatives.	Patient derived great advantage from this treatment; palpitation greatly reduced, so was the oppression in head; morphia acted well as a sedative; a removal to country made disease of heart almost disappear.	Great relief.
itus of heart in- sed, impulse ex- led, action heav- ; slight soufflet mpany. systole, rd at 2nd and 3rd on left side; left icle slightly ele- d, 2nd & 3rd ribs ging; sounds of rt low.	Violent palpitation, pain in region of heart; intermit. very weak pulse; sibilus at second and third ribs.	Leeches at first, then saline laxatives, followed by vegetable tonics.	The pain at heart, which had followed great exertion, was reduced by leeches and salines, and the general health was subsequently established by tonics and country air; three years after the patient was no worse.	Relief.
oud systolic sound embling "ha", athed very loud, dest at apex, ex- ding to third rib; reased action of rt.	Sense of pain; palpitation; disturbed health; p. weak, regular.	Numer. leeches to præcordia immediately, calom., Dover's powder, and colchi., iodide of iron.	Under first part of treatment, pain and inordinate action greatly abated, and pyrectic sympts. removed; iron gave vigour and "patience" to heart and improved general health; sound became greatly less loud and harsh.	Relief.
ery loud systolic nd, very prolong- resembling "ha" shly breathed out, sking first sound, rendering second nd difficult to be rd; loudest at rnum, level with rd rib; but heard rly over the entire st; moderate in- ase of heart's si- & impulse; veins neck rather full.	Moderate continuous over-action of heart; no other symptoms whatever; pulse regular, good size, and firm.	Pure air, a wet-nurse at first, occasional residence in the country, no medicine.	Has enjoyed good health, and has grown a fine blooming boy; but sound is the same, and action of heart still preternaturally great.	Perfect health.

No.	Name.	Age and Sex.	Habits of Life.	Family Disease.	Antecedent Diseases.	Duration of Disease.	Form of Dis
14	E. B.	18, F.	Destitute.	—	General debility, bad development. Small-pox in infancy. No rheumatism.	Some years.	Mitral v disease; derate hy trophy
15	E.	43, F.	Comfortable.	—	Large abscesses in groin, and in loins, discharging quarts of pus, now healed.	Six months certain, but probably more.	Dilatati moderate pertroph
16	S.	80, F.	Comfortable.	None.	Recent contus. of hip; great distortn. of spine, begun only a few weeks back, throwing the chin upon the right clavicle; obliterating the neck, distorting thorax, and reducing entire length about one quarter, rendering patient, formerly very tall, very short.	Unknown; discovered only a week or two before death.	Valvular with hy trophy. A outlet redu by distor of ches
17	J. C.	20, M.	Comfortable.	Weakly health.	Distortion of thorax begun in childhood, has increased latterly; thorax at heart decidedly depressed, to right of sternum protuberant.	Some years.	Moderate pertro., f moderate tortion of rax.
18	W. E.	20, M.	Comfortable.	—	None.	Congenital.	Modera hypertrop
19	C.	22, M.	Gymnastic exercises.	—	None. Front of thorax unduly prominent, from gymnastics.	Some years.	Moderate pertro. f gymnastic ercises
20	B.	26, M.	Exposure to cold.	Delicate health.	General delicacy from childhood. Moderate malformation of chest, with deficiency of left side. Want of beard and whiskers: singularly youthful appearance.	Some years.	Moderate pertro., excited tion, conn ed with formation chest, and ficient lft. s

ysical Signs.	Symptoms.	Treatment.	Effects of Treatment.	Result.
l hissing sound es first sound; se of heart in- d.	Papit., dyspnœa, cough, P. some- what weak, regul., weakness, pain in head, cong. of lung., vom. from irritab., occas. looseness.	Tincture of hops, with gentian infu.	Vomiting allayed, general health improv- ed, and less palpita- tion.	Relief.
ulse increased ce and extent; s clear.	Palpit. very se- vere and frequent, dyspn., weakness, P. small, hard, re- gular, some pain in heart formerly, occas. vomiting.	Morphia, for pain in heart, on one or two occas., conium and hyoscy. intern- ally, & lin. ammo. and leeches exter., to abate palpitat.	Pain held in check with morphia; palpita- tion much reduced by other treatment.	Relief.
d systolic bel- sound, loudest e above nipple; se increased; of exterior of dilated.	Moderate excite- ment of heart, recent œdema of feet.	Mild diuretics, hyoscyamus.	Nothing was attempt- ed in this case but to relieve symptoms.	Died a week or two after valvular murmur discover- ed. No necropsy.
pulse strong, ng, and unduly ded; sounds r dull.	Palpit., faintness, weak pulse, inter- mittent; occasional trifling hæmoptys.; moderate dyspeps.	Tonics, country air, exercise, iron.	No hæmoptysis of late, general health is improved, and over- action of heart moder- ated.	Relieved so as to attend to business.
pulse decidedly sed in extent orce; sounds r dull.	Occas. palpita- tion; occas. pain in region of heart; health good, pulse strong.	Pil. conii., mode- rate exercise and exertion, pure air and good diet.	Pain removed, palpi- tation somewhat re- duced.	Over- action of heart moder- ated.
pulse decidedly sed in extent rce; and action ng.	Palpitation occa- sionally, over-ac- tion constant., oc- casional faintness; P. weak, pallor of counten., pains in region of heart.	Quietude, seda- tives, chalybeates, abstinence from gymnastics.	Palpitation reduced, but over-action contin- ues, general health im- proved, less faintness.	Im- proved.
pulse increased ce and extent; is felt beating ht side of ster- n which direc- t is forced by ssion of left t præcordia.	Fits of palpitat., constant over-act., moder. dyspnœa, with dry rhonchus; pallor, feeble rapid pulse., irritability of stomach & vomit- ing; great emaci- ation and debility; irritability of bow- els from jalap, &c., chronic bronchitis, dry rhonchus.	Small dose of calomel with hyos- cyamus and aloes at first, followed by hyoscyamus and camphor, hops and liq. opii, lin. terebinth. extern- ally, iron.	Extraordinary bene- fit from treatment, no vomiting, though fits of palpitation; constant action of heart reduced, P. quiet, stronger, T. clean, appetite enorm- ous, patient and friends astonished at change, death being soon ap- prehended. The tinct. of hops with liq. opii was particularly useful in allaying irritability of stomach and sup- porting system; iron is well tolerated and is giving bloom to face.	Symp- toms re- lieved to only mo- derate extent; over- action of heart.

CASE OF CREEPING BUBO, ILLUSTRATING THE EFFICACY OF MERCURIAL TREATMENT.

By SAMUEL SOLLY, Esq., F.R.S., Senior Assistant-Surgeon to St. Thomas's Hospital, etc.

In the London Journal of Medicine for May 1849, I published an essay on Creeping Bubo; and as the following case illustrates the utility of a mercurial course as therein recommended, I am anxious to lay it before the profession as an addition to my former communication.

Case. The patient, a Cambridge student, aged 23, of good general health, had been, before I saw him, under the care of Mr. Robert Brown of Brixton Hill, to whom I am indebted for the particulars of the case.

April 10, 1850. A chancre appeared within the urethra, close to the frænum, and was shortly afterwards followed by a swelling in the groin. Caustic was applied by a hospital surgeon, who also ordered blue pill and extract of conium three times a day. The chancre healed completely in about a week; the swelling in the groin suppurated, and was opened on the 16th April, but it did not heal.

June 1. He went to Ramsgate, and to Brighton, and took baths for a fortnight. At the end of June he again went to Brighton. On his return, the sore in the groin was found to extend under the skin for an inch and a half; this was laid open in its entire length on the 30th of June.

July 16. The patient consulted me. I expressed my opinion that

ɔitation occasion- action always sense of flutter- ain darting from down left arm, rate dyspnœa, de- weak pulse, 88, ır, copious dis- e of blood from on two or three ons.	Copious hæ- moptysis once or twice, conges. of lungs, flatus.	Alteratives, hops, cinchona, stimulating em- brocation to chest and arm.	Palpitation somewhat reduced, and strength moderately increased; pain not materially re- lieved.	Some im- prove- ment.	
ɔitation, constant ction, hydrotho- nasarca of lower nities, dyspnœa, stion, aphthæ of e.	Anas. of lower extrem., hydro- thorax, cong. of lungs.	Hyoscyamus, spirits of nitrous ether, seton at præcordia.	Some relief from hyos- cyamus and spirits of nitre; none from seton.	Some relief for a time; death after a few months.	No examination.
stant over-action, pulse about 80, ntfits of extreme- ɔid action, with scarcely percep- pulse of from 200; the action heart resembled ing. and the foot the legs were d would move he wheel of a orthopnœa, œde- feet and ankles y, chronic irrita- f bladder, with ıe mucous urine, stion.	Œdema of feet and ankles some days before death, cong. of lungs, dry rhon- chus.	Morphia to allay palpita- tion; spirits of nitrous ether, squills, and sa- line diuretics; brandy, chloric ether; animal diet.	Morphia proved of im- mense service, would reduce pulse from 200 to 80; chloric ether in- duced extremely violent paroxysm of palpitation.	Great relief for a few days; death.	No examination per- mitted.

CREEPING BUBO. BY S. SOLLY, ESQ.

the disease was true *creeping bubo;* and that I was afraid it would not heal except under a complete mercurial course. As this was inconvenient, it was decided to dress the sore with mercurial ointment, and to give Plummer's pill at night, and iodide of potassium with sarsaparilla twice a day. He continued this treatment till the 20th of October; the greater part of the time being spent in a fine healthy spot in the moors of Scotland, and the patient leading a steady regular life, and not taking much exercise. When he returned from Scotland on the 20th October, the sore had extended, the edges were hard and more elevated, and the ulceration creeping under the skin in a semi circular form, healing a little in some places, but extending a little in others. I now recommended a more decided mercurial course; but it was agreed that it should be postponed for six weeks, to enable the patient to get his degree at Cambridge. In the mean time, he was to take the bichloride of mercury with sarsaparilla.

November 27. He returned from Cambridge, with the sore in about the same state as six weeks ago. He was now confined to the house, and commenced rubbing in a drachm of the strong mercurial ointment every night. As soon as the mercury affected his gums, which took place in a few days, the sore began to amend, and continued to heal steadily. It was healed in five weeks after the rubbing in was commenced; and some thickening of the cicatrix was removed by a continuance in the use of the mercurial inunction for a week longer.

St. Helen's Place, Bishopsgate, March 1851.

OBSERVATIONS IN REPLY TO DR. GEORGE GREGORY ON EXANTHEMATIC RELATIONSHIP.

By ALEXANDER KNOX, M.D., Physician to the Dispensary, Strangford, County Down, Ireland.

My attention has been drawn to two papers written by Dr. George Gregory, Physician to the London Small-pox Hospital, which were inserted in the *Medical Times* (on the 18th of January and 1st of March in the present year), on what he terms Exanthematic Relationship; but principally devoted to the criticism of my views on the subject of Vaccination, which first appeared in the pages of this Journal in November and December last, and have subsequently been published in an independent form. I should gladly have avoided any controversy on this subject; but as Dr. Gregory has specifically appealed to me for an answer, I comply with his demand, limiting myself, however, to a dispassionate examination of such scientific points as seem to require notice, and avoiding all comment upon the tone and manner which he has adopted in canvassing my opinions. I must premise, however, that I do not subscribe to Dr. Gregory's mode of stating my arguments; but prefer to be the exponent of my own views. It will therefore be necessary for me to rectify some misconceptions—I will not term them misrepresentations—into which he appears to have fallen.

It is admitted by Dr. Gregory, that the experiments of Mr. Ceely were considered by many as decisive of the question of the identity of cow-pock and small-pox; and that this doctrine therefore has of late been very generally conceded. The state of professional opinion on the subject is here, I apprehend, correctly stated, and I shall therefore content myself with adducing in its confirmation a single extract from the letter of a physician of long standing and much experience, which is now lying before me: "I did not suppose that any one was of opinion that variola and vaccinia were not the *self-same disease*, the symptoms of course being modified in the latter", etc., etc. But however others may think on the subject, Dr. Gregory's ideas, according to his own testimony, have undergone no change, and he still maintains unreservedly that the diseases alluded to are not identical. It therefore becomes necessary to examine a little the train of reasoning, which he has adopted in support of his view of the subject.

The first of his arguments to which we shall advert is, "that no direct experiments, as far as his observation extended, had proved that cow-pock can be communicated from man back to the cow." This was published in 1838; yet the experiments of M. Fiard had distinctly shewn, that retro-vaccination could be effected in 1825, as it had been in the beginning of the century, when vaccination was first introduced into France; and the fact had also been established by Valentin, Sacco, Frank, and other competent authorities. At any rate, the experiments of Prinz and several recent observers have established the point beyond controversy. This argument, at all events, has, we presume, been abandoned by Dr. Gregory, as we find him actually

contending for the superiority of the virus[1] "renovated by passing the vaccine lymph again through the body of the cow".

The next statement of Dr. Gregory requiring comment is, "that the doctrine of identity, or non-identity, does not, and never did, influence the belief in the virtues of vaccination". And he elsewhere asserts, that identity is "the groundwork of my faith, the pivot on which my reasoning turns", and "the polar star of vaccine pathology". In replying to these assertions, it is necessary to shew, in the first place, that Dr. Gregory has not fairly stated the argument which he professes to answer; for he would make it appear, that the doctrine of identity constitutes my chief ground for belief in the protective influence of vaccination. But on reference to my papers,[2] it will distinctly appear, that my arguments are grouped as follows: 1. Popular experience, as to the immunity enjoyed by those who have casually contracted Cow-pock from the cow, horse, or camel; 2. The identity of cow-pock and small-pox *an argument in favour* of the protective influence of vaccination; 3. Testimony in favour of the protective influence of vaccination; and, finally, evidence as to the actual results of vaccination, which I have in terms stated "*to be the most satisfactory, and after all, the only conclusive method of determining the true value of cow-pock.*"[3] And again, at page 24, it is distinctly stated, that the protective influence of cow-pock has been advocated on the following grounds: 1. The power which it confers of resisting the contagion of the casual disease; 2. Of resisting the effects of variolous inoculation; 3. Of resisting the effects of re-vaccination. This explanation will enable the reader to judge whether I have good reason for preferring to be the exponent of my own views. But although identity is not the "groundwork of my faith", I still continue, with great deference to Dr. Gregory, to look on it as a strong corroborative argument in favour of the protective influence of vaccination; and until he shall point out some disease which, by its passage through the system, prevents the subsequent attack of another disease, I shall venture to maintain, that the disproval of identity would fairly tend to shake our confidence in the defensive power of vaccination. But as far as the opinion goes, that the result of experience is the best proof of the protection afforded by cow-pock, there is no difference of opinion whatever between Dr. Gregory and myself. His whole argument is, therefore, merely an *ignoratio elenchi;* but if he assert that the proof of the doctrine in question may not be strengthened by corroborative arguments, there we unfortunately disagree.

But to pass on to another point of Dr. Gregory's criticism, regarding the pustular character of cow-pock, it is necessary to shew, in the first place, that, by quoting a part only of my statement, and placing another part in italics, a meaning is conveyed different from what I have really expressed in the original. The quotation to which I allude is this, "although cow-pock is considered rather a vesicular than a pustular malady, the vesicle becomes turbid towards the close, *and actually secretes genuine pus. Such is the usual progress of the genuine cow-pock.*" By this partial quotation and typographical device,

[1] Medical Times, March 1, 1851.

[2] London Journal of Medicine for 1850, p. 1044 et seq.; and Pamphlet, p. 10 et seq.

[3] Ibid., p. 1138; and Pamphlet, p. 20.

it is made to appear, that the last quoted clause refers exclusively to the progress of the vesicle; whereas a glance at the original in my pamphlet (page 14), will shew, that it has reference to the entire preceding description of the phenomena of cow-pock. As I should be very sorry to accuse Dr. Gregory of intentional misrepresentation, or of want of candour in stating the arguments of an opponent, I shall set down this misconception also simply as a mark of the haste with which he has evidently written. But still we are directly at issue, on the point as to the secretion of pus in cow-pock; for, although he qualifies his objection by stating, that he has not met with this as the *normal* character of cow-pock (he does not say that he has never met with it), yet he expressly affirms, that one of the essential differences between cow-pock and inoculated small-pox, is the invariable tendency to pustulation of the latter, and the truly vesicular character of the former. And he adds, "if I saw the genuine cow-pock secreting genuine pus, I should very soon become a convert to Dr. Knox's theory of identity; but, as I do not see the fact, I may be excused for demurring to the theory founded on it". Here I may be permitted to state, that the theory, whatever confirmation it may gain from the fact to which Dr. Gregory alludes, is not founded on it; it has other and much more substantial foundations—but let this pass. It cannot escape notice, however, that the other arguments adduced by Dr. Gregory against the doctrine of identity cannot have any great weight in his own mind, as he candidly enough admits, that if he were satisfied as to the correctness of my statement on the last mentioned point, he should soon adopt the theory which I have advocated. It appears of consequence, therefore, to examine for a little the question at issue, which is one of fact. The result of my own observation is explicitly stated in the quotation above alluded to, viz., that "although cow-pock is considered rather a vesicular than a pustular disease, the vesicle becomes turbid towards the close, and actually secretes genuine pus"; a description which, with equal correctness, might be applied to small-pox; for it first secretes lymph, and subsequently pus. No doubt there is usually a difference as to the quantity of the purulent matter, but this does not invalidate the truth of the general description. So far, therefore, from seeing an essential point of difference between the two forms of the malady, in the character of the secretions of the pock, I should refer to their similarity in this respect, as an additional proof of their identity, were additional proof wanted of a fact, demonstrated, as I conceive, by direct and conclusive experiments. As I do not, however, feel disposed to place my humble and unaided testimony in direct opposition to the high authority of Dr. Gregory, I shall here briefly refer to a few out of many distinguished writers, who concur with me as to the characteristic secretion of the cow-pock. Not to mention that Schlesier, Heim, and perhaps the majority of writers, employ the term pustule in speaking of the cow-pock, I find that Jenner, long since, was not singular in pointing out the close resemblance of the vaccine pustules, in certain stages, to the pustules of small-pox; for Soemmering, and C. L. Hoffmann, certainly no inaccurate observers, have made the same observation. A clever anonymous writer, in the *British and Foreign Medical Review* (No. xvii, p. 94), thus states the point in debate. "The lymph, though

at one time thought to retain its transparency uninjured, is said to become turbid and puriform after the full development of the pustule". Dr. Mason Good, likewise, in his description of the natural form of cow-pock, or as immediately received by milking, expressly asserts that the fluid, at first limpid, afterwards becomes opaque and purulent. And Dr. Elliotson, who it is presumed will be considered a competent authority, in speaking of vaccinia, says that, "although there are only vesicles at first, the contents become so turbid, that at last there is *genuine pus*". The testimony of Cazenave and Schedel is to the same effect; "le fluide contenu dans la vesicule devient purulent", etc. But it is unnecessary to accumulate further testimony on this head, as the question, after all, is one of fact, which the reader, as opportunity may occur, can determine for himself; and in which he would receive much assistance from the minute description of the morbid anatomy of small-pox, written by Petzholdt. Dr. Gregory has further expressed his utter inability to understand the passage in which I have stated, that in general the character of the malady has been rendered infinitely milder by its transmission through the cow. Now if he will compare the characteristic features of small-pox with the symptoms which follow the disease produced by the lymph derived from a cow, after inoculation with small-pox matter, I think he will not be at any loss to comprehend my meaning.

Again he questions, but hesitatingly, and with more caution, my reference to the occasional severity of the cow-pock occurring in the cow: not venturing absolutely to deny the severity of the epizootic which occurred at Moorshedabad, he contents himself with stating, that I ought to be aware how much doubt hangs about these cases. But experience might have taught Dr. Gregory, that to throw doubt or discredit on facts that come in the way of a favourite theory, although an easy, is not in the end a very successful mode of controversy. At one time Dr. Gregory maintained, as we have already pointed out, that no distinct experiments had proved that cow-pock could be communicated from man back to the cow. And he further asserted, that the experiments of Dr. Sonderland, and others instituted in Egypt, which shewed the practicability of transferring small-pox, from man to the cow, were "incorrect, if not altogether fabulous". Would Dr. Gregory make the same assertions now? We presume he would not; but, at all events, he can no longer repeat the assertion, that "the theory which would explain the preservative power of the cow-pock, on the principle of its being small-pox, which, in passing through the body of the cow, had become modified, is still unsupported by direct experiment." He may also probably have altered the opinion, "that the hope entertained by some sanguine physiologists, that, in the possible loss of the present stock of cow-pock, small-pox might be made to furnish its antidote, is altogether illusory." But that this hope is not illusory, has been proved by the experiments of Thiele, Ceely, Estlin, Badcock, and others; for many thousand persons have been successfully vaccinated with the lymph taken from cows inoculated with small-pox matter: indeed, the point has been conceded by Dr. Gregory himself, who states, that he would as soon use vaccine virus, generated in the cow by the inoculation of small-pox matter, as that which arises in the cow spontaneously. Mr. Badcock alone, whose

persevering energy in elucidating the point under discussion is worthy of all praise, has kept up, during the last ten years, a succession of experiments upon more than a hundred cows, and has thereby not only supplied lymph to many other practitioners, but has himself vaccinated more than eight thousand patients, without a single failure. He therefore, justly in my opinion, considers the identity of the two diseases to be fully proved by his experiments.

Having thus far attempted to dispose of various objections, the next point which I shall briefly notice, is the allegation with reference to the grouping of the phenomena of inoculated small-pox in the tabular form, in my pamphlet (pp. 19, 20),—that all, to use the language of Dr. Gregory, is inaccurate. In criticising this part of my treatise, he says that the papula, in inoculated small-pox, is as much confined to the locality of the puncture as in cow-pock. Perfectly true, no doubt; but on reference to the fifth page of my pamphlet, it will, I think distinctly appear, that I was already in possession of this information. It is scarcely to be expected that the phenomena of a disease can be as minutely described in a tabular form, as in a detailed description, and I admit that the table in question might be more lucidly arranged; but I shall content myself with a simple denial of the assertion, that in drawing it up, I was influenced, even in the slightest degree, "to assimilate the course of cow-pock to that of inoculated small-pox." The clause "generally few in number", which I have used in the table, refers to the secondary eruption; and I have yet to learn that this secondary eruption, although frequently more diffused, may not be occasionally confined to the vicinity of the punctures. And with regard to the criticism on the statement, that the areola appears on the *ninth or tenth day*, and that, by the tenth day, the primary pustule is full of matter; if mistaken in this respect, I can at least allege that I am not solitary in the error, as I can show by appealing from the opinion of Dr. Gregory, writing hastily and captiously, to Dr. Gregory, writing in a calm and philosophic spirit. For, referring to his own description, I find it to run as follows. "The incision, when viewed through a glass, now appears surrounded with an infinite number of small confluent papulæ, which daily increase in size; on the *tenth day* an areola, or circle of inflammation, forms around the inoculated point, *now* distended with matter. This areola is irregular in shape, and in its progress becomes interspersed with numerous minute vesicles. And again, occasionally on the *seventh*, but oftener on the *eighth day*, rigors occur, accompanied sometimes with faintishness, sometimes with pain of the back, headache or vomiting. The patient complains of a disagreeable taste in his mouth, and the breath is offensive, after which the eruption shews itself."[1] Neither am I solitary in the opinion, that, as a general rule, there is no "secondary fever"; in confirmation of which I only consider it necessary to quote a single authority, that of Dr. Watson, who expressly asserts that it is "*generally slight, or wanting.*"[2] But it will probably be thought that enough has been said on this point.

I pass on to the criticism on my assertion, that "the deterioration of the vaccine virus is a mere hypothesis." In opposition to this

[1] Cyclop. Pract. Med., vol. iii, p. 750. [2] Lectures, 3rd Ed., vol. ii, p. 789.

view, the authority of M. Bousquet is quoted, in reliance on which it is asserted, "that the experiments performed in Paris, in 1836, most distinctly *proved?* that the lymph was improved most materially in all its characters". Now I am fully aware of the experiments referred to; and without questioning the facts, it is open to me to question the validity of the inferences which have been deduced from them. But having told his readers so much, Dr. Gregory might also have apprised them, that the greatest diversity of opinion prevailed amongst the members of the faculty, who witnessed the results of the experiments alluded to. Some of the members of the Academy took the same view as Dr. Gregory, and drew the conclusion, that the original lymph had degenerated, whilst others inferred, as I do, that the size and elevation of the pustules is no infallible criterion of the energy of the virus, and that much variety, in this respect, may be produced by peculiarity of constitution, the state of the atmosphere, and other causes, without attributing it to deterioration of the lymph. At the same time I am quite aware, and have expressly stated, that vaccine lymph may be deteriorated by ignorance or carelessness; but I repeat the statement, in full confidence in its truth, that it is a mere hypothesis to assert that any deterioration has taken place in its qualities, simply by transmission from person to person. I do not question the fact, that many imperfect specimens of vaccine virus may be found; but, on the other hand, I have no doubt, from the testimony which might be adduced, that lymph may be found in the most genuine form, although in continuous use from the time of Jenner. My opinion may be deemed of little weight on this point, as contrasted with the high authority of Dr. Gregory; but the statement of such observers as Dr. Watson cannot be lightly passed over; and we find this distinguished physician thus expressing his views on the point under discussion. "For one year I had a seat as the Senior Censor of the College of Physicians, at the National Vaccine Board, and I then had opportunities of satisfying myself that lymph, which had been transmitted without interruption from person to person, ever since the time of Jenner, continued to generate as perfect a cow-pock vesicle as at first". To adopt the language, therefore, of a clever writer,[1] "It remains, we think, still to be proved, that where all Jenner's directions have been attended to, the vaccine lymph has undergone the smallest deterioration". Were we even to admit that it has become effete or deteriorated, we do not believe that the proposal brought forward at one time to remedy this effect, by increasing the number of punctures, is founded on any substantial grounds; on the contrary, we look on it as altogether illusory, and we think it would require strong evidence to shew that ten, twenty, or even forty punctures, with imperfect lymph, would have the same preservative effect as a single vesicle produced by genuine virus. Before dismissing this part of the subject, I may be permitted to allude to Professor Hering's statement. This eminent writer informs us, that a very great variety of opinion exists as to the value of lymph produced by retrovaccination. Some believe, with me, that there is no difference in efficiency between it and that hitherto in use; others,

[1] Brit. and For. Med. Rev., No. xii, p. 494.

as Prinz and Bousquet, have come to the conclusion that its quality is improved by retransmission; whilst a third party, of whom Professor Ritter is one, are of opinion that it is less active than virus of spontaneous origin. Under such circumstances it is not reasonable to expect that a dogma, emanating even from the highest authority, will pass unquestioned.

But it has been asked why, if the two diseases are identical, so many cases of small-pox occur after vaccination, and only an infinitesimal proportion after a primary attack of the casual disease? Were the fact really as stated, it would be a sufficient reply to contrast the immense preponderance of the vaccinated, in point of numbers, over those who have the disease in the casual form. It is therefore not sufficient to shew, that the absolute number of recurrent attacks is greater after vaccination than after casual small-pox; to give any force to the objection we are discussing, it should further be clearly shewn that the relative proportion also is in the same circumstances greater. In short, it seems to come to this, that cases of small-pox, after small-pox, are less numerous than after vaccination, simply because the primary cases of casual small-pox are also infinitely less numerous than cases of vaccination. There is also another source of fallacy in drawing a conclusion, which should be pointed out. Many of these alleged cases of small-pox occur after *imperfect* vaccination; and are therefore, in reality, primary, and not recurrent attacks of the disease.

After writing thus far, I have read in the *Medical Times* of the 8th, and the *Dublin Medical Press* of the 12th of March, some observations of Dr. Gregory on the subject at issue, which, if correctly reported, seem to demand a passing observation. They arose out of a report of some cases of recurrent small-pox read at the Royal Medical and Chirurgical Society, on the 25th Feb. last, by Dr. Webster and Dr. A. P. Stewart. In one instance, although vaccination and revaccination had been practised, and, in others, though the patients had previously had small-pox in its natural form, yet the disease recurred a second, and in one instance a third time, and proved fatal. The cases alluded to are very interesting, and, in my opinion, strongly corroborative of the views expressed in my pamphlet (p. 38), that the constitutions of certain individuals are "absolutely beyond the influence of any protecting agent whatever".

Many of the failures of cow-pock are thus readily susceptible of explanation; for, in these instances, although vaccination did not protect the patient, a previous attack of the casual disease was equally unsuccessful in preventing its recurrence; and in one instance, as already stated, even a second time. In the course of the debate that took place, it appears to me, that the reference of Dr. Mayo to the epidemic of small-pox in Edinburgh, in which the disease was *remarkably more fatal among the inoculated* than the vaccinated, constituted a very satisfactory reply to the dogma of Dr. Gregory; "that inoculation imparts full protection, whilst vaccination does not protect, except up to the age of puberty." Possibly, however, his opinion may not have been correctly reported; but if it has, on this point at least, "his ideas have not remained unaltered"; for elsewhere he has stated, that "permanent security is the *law* of the animal economy, and *temporary*

security the exception".[1] And I think it will be found on investigation, that Dr. Gregory's allegation, that modified small-pox occurs only in grown up persons, is equally irreconcileable with the facts of the case. Wendt, and several other writers, mention instances where the disease took place before puberty; and Dr. Snow's experience is to the same effect. Dr. Thomson found the modified disease to occur at every period after vaccination. In my own practice I have met with at least two unequivocal cases; the patients being in the ninth or tenth years of their age. Of two practitioners, of extensive experience and sound judgment, whom I have consulted on this very point, one writes, that "he does not remember to have met with a dozen cases of that disease (modified small-pox) under the age of puberty; and the other informs me, that, "with one exception, all the cases of modified small-pox, occurring after vaccination, which he had met with, took place before the age of puberty, the entire number not exceeding twenty". I could produce much more evidence on this point, if more were required, to shew that the *ipse dixit* of Dr. Gregory is absolutely erroneous.

Some of the statistical information, brought forward in the course of the debate alluded to, satisfactorily confirms the great value of vaccination; and the results afforded by the epidemic, referred to by Dr. Mayo, would even go to prove that vaccination, as a measure of protection, is superior to inoculation. But without going this length, if it be only equally defensive, its superiority, on other grounds, cannot be questioned; and, as I have elsewhere stated, "it is not reasonably to be expected, that cow-pock, formerly believed, and more recently proved, to be in itself only a modified form of small-pox, should impart any greater amount of protection than the more severe form of the malady" (Pamphlet, p. 38); an opinion which, I am gratified to find, has the support of so distinguished a physician as M. Chomel.

But there is another point on which it would appear that the ideas of Dr. Gregory have not remained unchanged. At the debate in question, he is reported to have said that "he regarded re-vaccination as nothing more than a means of satisfying the patient; it had no real preventive influence". This appears to be the opinion of Dr. Gregory in 1851. But that it was not so some years ago, will clearly appear from the following quotation: "The practice is one from which no harm and much benefit may be expected. If no effect follow, the security of the patient is rendered doubly sure. If vesicles arise, and the disease goes through all, or some part of its usual course, that security may be reasonably considered as renewed." As I have, in the essay which is the object of Dr. Gregory's criticism, fully explained my own views as to the value of revaccination, it is not necessary to restate them here. It would, however, be satisfactory to learn on what sufficient body of statistical information Dr. Gregory has so completely changed his opinion; and the production of the necessary evidence might moreover tend to restore confidence in his authority on such questions, which must necessarily be shaken by discrepancies of opinion so glaring as those alluded to.

I have already referred to Dr. Gregory's scepticism regarding the nature of the disease prevalent amongst horned cattle at Moorshedabad

[1] Cyc. Prac. Med., vol. iv, p. 414.

in 1825. In that scepticism I do not concur; but supposing it to be well grounded, there is no lack of other evidence, probably sufficient to satisfy every unprejudiced enquirer of the occasional severity of the disease amongst animals of that class. In the variolous epizootic occurring in Bengal, which is referred to in the appendix to the second volume of Baron's *Life of Jenner*, it appears that extensive inoculations from the diseased cows produced not the mild vaccine vesicle, but an *eruptive malady of the true variolous character*. Still later, Mr. Wood, in Corbyn's *India Journal* (March 1838), details several cases, in which lymph taken from the cow produced a disease of an eruptive character, so severe, that he even goes the length of saying, that variolous inoculation at such a time produces a safer disease than vaccination.[1] Various other severe epizootics, occurring at different eras, are on record, as the pestilential eruptive disease described by Dr. Layard in the *Philosophical Transactions* (1780), which ran its course in Holland and Flanders; that which prevailed in Picardy, recorded by Vicq d'Azyr; to which we may add the cases occurring in 1825, narrated by Dr. Baron, on the report of Mr. Tiley, in the first volume of the work already mentioned.

Before the publication of the experiments of Ceely and some others, many writers, though strongly convinced of the identity of small-pox and cow-pock, candidly admitted that a link was wanting to render the chain of evidence complete; and even Dr. Gregory, then writing more cautiously than now, was evidently fully aware of the nature of the conclusion to which such experiments, if successful, were plainly calculated to lead. Having endeavoured to throw discredit on the researches of Sonderland and others, we find that, on the very ground of their alleged want of success, he drew the inference, which will be best stated in his own words: "It remains *therefore* a very *questionable* point, whether these disorders can be essentially the same." And now when the experiments of Thiele, Badcock, Estlin, and Ceely, have rendered it impossible to deny, or even to question, the practicability of transferring the small-pox to the cow, Dr. Gregory's ideas, whilst all others around him have been convinced, still remain unchanged. And what his ideas on this particular point were, he has left no room to doubt, for he has stated in terms, that "*cow-pock and small-pox were as essentially different as small-pox and measles*". Admitting now, as I believe Dr. Gregory does, the facts so clearly elucidated by Ceely and others, he still denies that they warrant the conclusion generally drawn, viz., that cow-pock *implies the same thing*, or is *identical with small-pox;* and it therefore becomes necessary to inquire in what manner he attempts to explain the experiments alluded to, since the actual results have been established beyond the reach of cavil. This explanation I shall give in his own words. "I affirm that one malady is capable of producing or developing, by inoculation, in an animal of a different kind, another malady of an *allied* nature, but still specifically distinct." But affirmations, unsupported by facts, go for little in the present day. To give any weight to his theory, Dr. Gregory should have specified some diseases which, being transferred from one

[1] See Dr. Baron's Letter in Brit. and For. Med. Rev., No. xiii, pp. 295-6-7.

animal to another, produce other diseases specifically distinct in their nature. For our part, we profess our total ignorance of any such diseases. It is sufficiently established by the writings of Elliotson and Rayer, that the virus of glanders will communicate a disease from the horse to man, but it has never hitherto been maintained, as far as my information extends, that the disease thus transmitted is not glanders, but one, to adopt the definition of Dr. Gregory, of an allied nature, but specifically distinct. Hydrophobia is another disease transferable from the dog and other animals to man; but the latter, when thus infected, has been always hitherto at least believed to labour under veritable hydrophobia, and not under a specifically distinct disease. But Dr. Gregory attempts to support his theory by reference to the variola ovina, the sheep-pox of these countries, and the "clavellée" of our continental neighbours. Now even assuming all the facts on which his reasoning, as regards sheep-pox, is based, to be true, there is little if any weight as affecting the identity of the diseases; and that little has been sufficiently disposed of in a letter, signed "Inquisitor", in the *Medical Times* of the 15th of February last. But several of the assertions relied on require further investigation before they can be admitted into the class of facts. When Dr. Gregory has supplied the necessary evidence on these points, it will be soon enough to reason on them; for the present, therefore, I shall content myself with enumerating a few of the assertions to which I have alluded as requiring confirmation.

1. That "these disorders of the horse and cow, respectively, are *always* mild or benignant disorders". 2. That the "sheep-pox is the offspring of an allied miasm". 3. "Matter taken from a sheep affected by this disease, and applied to man, appears as cow-pock; but vaccine lymph, taken from the cow, has no effect on the sheep, nor has the sheep-pox the property of affecting the horse or cow." 4. "It does not appear that human vaccine will affect either the horse or sheep." 5. We have "the acrid miasm of the sheep producing a mild disease in man". This last assertion has, no doubt, the support of Sacco; but Ceely, Marson, Simmonds, and Hurtrel d'Arboval, have been led by experiment to a directly contrary conclusion; viz., that ovination will not communicate the disease to man, either in a *mild* or acrid form, as appropriately pointed out by "Inquisitor", the writer already referred to; who has also saved me the trouble of examining, at length, the vague and irrelevant chemical analogies by which Dr. Gregory labours to give support to his theory. But, before leaving this part of the subject, I shall just refer to one passage in Dr. Gregory's first communication, as a specimen of his manner of elucidating his theory.

"It requires no great stretch of imagination to conceive, that the primary exanthematic miasm, so largely disseminated throughout the animal kingdom, is composed of two or three ingredients, which variously combined, appear in the several forms of small-pox, cow-pox, chicken-pox, sheep-pox, and equine grease; while the elementary changes convert the miasm into the parent of measles, scarlatina, the pestis bovina, and the canine distemper. Nay, it is further very conceivable, that cholera, the dreaded Asiatic pestilence, is an offshoot of the same miasmatic root, which, mollified by the lapse of

ages, may at length display features which will give it rank amongst the exanthemata."

It will scarcely be expected that I should offer any observations on such conceptions of the imagination as these, and they may very safely be left to the disposal of the professional world. Indeed, fancies so wild seem better adapted to an age when it was a serious subject of debate, whether one of the French kings should be bled on the right side or the left, than to the present enlightened era.

But further on, Dr. Gregory describes the small-pox and cow-pock virus as being also generically allied, but specifically distinct; and he winds up his theory by a quotation from M. Bosanquet, with reference to the identity of the diseases: "Il n'y a pas entre elles identité de nature, mais il y a reciprocité d'action." And this is Dr. Gregory's mode of explaining the lucid, beautiful, and conclusive experiments of Ceely. Calculated, as they seem to be, to demonstrate to every impartial mind that cow-pock and small-pox are essentially the same disease, to Dr. Gregory they only prove, that they are not identical, that they are generically allied, but specifically distinct, not possessing identity of nature, but reciprocity of action!

Dr. Gregory has further attempted to show that the non-identity of the diseases in question may be proved by a strictly logical inference, and his syllogism is thus expressed: "Identity means sameness; if they are the same diseases, they cannot have differences; but cow-pock and small-pox have differences, and therefore they cannot be identical." But this mode of arguing would manifestly prove a great deal too much. For instance, mild and malignant cases of scarlatina have very obvious differences, and therefore accordingly they cannot be identical. But to take an example still more to the point. Casual and inoculated small-pox have unquestionably differences, and if we were to adopt Dr. Gregory's syllogistic argument, they cannot be identical; and yet in both these instances, I feel satisfied that Dr. Gregory will assent to the identity of the maladies referred to. This style of argument is certainly puerile enough; but as I should be sorry to accuse Dr. Gregory of quibbling, it is manifest that if he is in earnest here, he overlooks a fallacy, which even the merest sciolist may detect.

Having thus passed briefly in review the comments of Dr. Gregory, I do not think it necessary to restate here the arguments on which I have urged the identity of small-pox and cow-pock. I shall therefore content myself with repeating in very few words, the sum of my belief on this head. When small-pox virus, taken from the human subject, produces by inoculation a specific disease in the cow, I maintain that the disease thus produced is small-pox; and when this disease is retransmitted by vaccination to the human subject, I believe that the resulting malady is, *ex necessitate*, small-pox also. These inferences, it appears to me, are strictly deducible from the experiments of Badcock, Thiele, and Ceely, and it must be left to the professional reader to contrast them with the theoretical explanation of Dr. Gregory, "that one malady is capable of producing by inoculation, in an animal of a different kind, another malady of an allied nature specifically distinct, not possessing identity of nature, but reciprocity of action". I of course admit, and have distinctly pointed out, the modifications to which the disease is liable;

but I do not admit that these are of such a character as to afford any valid argument against the identity of small-pox and cow-pock. I fully concede that various circumstances may modify the phenomena resulting from the transmission of the small-pox virus; but *I do not admit that any circumstances can destroy its identity, or confer on it the power of producing any other disease than small-pox.* I therefore feel constrained altogether to refuse my assent to the affirmation of Dr. Gregory, that one malady is capable of producing in an animal of a different kind, another malady specifically distinct. On the contrary, after deliberate reconsideration of the whole subject, I think the facts warrant me in supporting the views expressed in the petition to Parliament, emanating from the Provincial Medical Association, viz., that the cow-pock is "an affection of a true variolous character, demonstrated by historical evidence, as well as by direct experiment, human small-pox having been recently communicated to the cow by inoculation, and the result having been the production of a variolo-vaccine lymph, possessing all the properties of the original vaccine disease."

In conclusion I have only to state, that the discussion, in which I have been reluctantly engaged, was forced upon me. Although necessarily commenting freely on the views of Dr. Gregory, where I believed them to be erroneous, I have passed by many points, in his hasty effusions, which appear open to objection. My sole motive, in writing on the subject, has been to advocate, at an appropriate time, views which I consider to be true, and which I believe deeply to affect the social welfare. And although I have the misfortune to differ with Dr. Gregory, whose authority generally I respect, and have shewn no wish to underrate, yet many letters, now lying before me, encourage me in the belief that I have neither erred in the views which I have adopted, nor in the time selected for their advocacy.

Strangford, Ireland, March 1851.

BIBLIOGRAPHICAL RECORD.

General Pathology, as conducive to the establishment of Rational Principles for the Diagnosis and Treatment of Disease ; a Course of Lectures, delivered at St. Thomas's Hospital, during the Summer Session of 1850. By John Simon, F.R.S., etc. pp. 288. London : 1850.

Our readers are doubtless in some measure already acquainted with the contents of these Lectures, seeing that they first appeared in the pages of the *Lancet*. We are, however, tempted, in spite of this, to bring them again somewhat prominently forward ; and in so doing, we bear the strongest possible testimony to our sense of their value and importance.

The First Lecture is of an introductory character. In it Mr. Simon labours strenuously with the difficulties of definitions. We shall not follow him in his struggles. What he says, he says well, and very much to the purpose ; but agreeing with him, as we do, that a matter admits of philosophical definition only when its investigation has been completed, which is very far indeed from being the case with the science of pathology, we hold ourselves fairly exonerated from the trouble of striving after the unattainable.

The Second and Third Lectures are devoted to the examination of the Condition of the Blood in Disease ; a subject, the importance of which it is scarcely possible to over-estimate. Moreover, it is a most intricate branch of the inquiry, for, as Mr. Simon most correctly observes : " A chief difficulty in the study is this ; that the blood undergoes changes of its own—undergoes what I can hardly call anything else than a process of growth. In addition to receiving new matter from the food, and old matter from the tissues,—in addition to feeding the several organs, and supplying the several excretions of the body, it does also itself undergo, as I have said, progressive changes of its own, analogous to the growth of the solid tissues. For the new materials which are derived to it from the food are not *blood* at the time of their addition ; they are crude, immature products, which subsequently ripen within the stream of the circulation, under the influence of the maturer blood, and conformable to its composition. To some of you, perhaps, the view here suggested, of the blood undergoing development akin to growth, may be new and strange. There is an early prejudice, which makes us consider solidity of structure an indispensable preliminary for the residence and manifestation of life. Still, in spite of that prejudice, and in spite of the fluidity of the blood, you may safely believe that that red fluid is a living, growing mass ; that the process of blood-formation is not the mere infusion of certain ready-made materials from without, but is as truly a process of growth as the development of cartilage or muscle.

" If the power of resisting change—if the power of converting things to its own type, and perpetuating its own constitution—be signs of life in an element or portion of the body, I know none which possesses these qualities in a higher, if in so high a degree as the blood. And further, in recalling its anatomy, you will be confirmed in this view. You will remember, that in all other elements of the body, the abundance of cell-development which you meet with, measures the activity and constancy of growth ; and if you put a drop of blood under the microscope, and compare it with a patch of equal size of liver, or of brain, you are at once enabled to judge how immeasurably greater is the developmental activity in the blood ; or if you look at a drop of fluid from the thoracic duct, you observe myriads of cell-germs there—germs which it is the chief, and perhaps the only, object of the lacteal and lymphatic systems to provide, and which attain their maturity, and fulfil their purpose, only when received into the blood. And not only does the blood live and grow ; but, in the mature animal, its life and growth must

precede all other life and growth in the body ; for first *it* grows, next other organs grow at its expense." (pp. 21, 22.)

Besides this, the rapidity with which changes in the blood occur, and the complex nature of the fluid itself (containing as it always does imperfectly formed particles, particles fully developed, and particles worn out by use), add greatly to the difficulties which beset our path.

In following out the subject of blood-diseases, our author examines, *first*, those which depend on morbid ingestion ; *secondly*, diseases depending on increase, arrest, or alterations of the excretions ; *thirdly*, diseases depending on modification of the blood's own growth and development.

The *first* are illustrated by the action of *poisons*. The *second* are exemplified by the *retention* and *accumulation* in the blood of matters which ought to be excreted, as carbonic acid, bile, urea ; and by the alterations produced by certain new, artificial, or otherwise abnormal excretions, such as the *inspissation* which results from the excessive discharges of cholera, and the *attenuation* following upon hæmorrhages, protracted suppurations, etc. The *third*, which may be considered as primary diseases of the blood, are examined at considerable length. The *corpuscles* may be proportionately increased, which is the condition in plethora ; or diminished, as in chlorosis. The *serum* may be altered in regard to the respective quantities of salts and albuminous elements, and probably the changes here are the most important of all, though our knowledge of them is not as yet very precise. Among the most common, and at the same time most interesting of these, are the variations in the quantity of *fibrin*. Mr. Simon inclines to the view adopted by Zimmermann and a few other physiologists, that the fibrin, instead of being the nutritive element in the blood, rather occupies the same position as the extractive matters, and, like them, is the result of decay of the blood itself, or of the waste of the tissues. We conceive that this view is quite untenable. If it were true, how are we to explain the well known fact, that the quantity of fibrin is greatest in the chyle of the thoracic duct, having appeared gradually during its progress from the lacteals ?

Be this as it may, many evils result from the presence of an excess of fibrin in the blood. Among these, Mr. Simon mentions the existence of fibrinous concretions in the spleen, the kidneys, and the liver ; and he attributes to the same cause the occurrence of vegetations on the cardiac valves, which are so frequently found in cases of acute rheumatism, and are generally attributed to endocarditis.

" As the question ' How do these valve-diseases originate ?' is one of the greatest practical importance (for it must materially influence the method of treatment), I shall enter at length upon the theory of their formation.

" The general opinion, which till very lately has been unquestioned, is, that the lining membrane inflames, and pours out lymph (just as the pleura or pericardium might do), and that thus these vegetations are true *excrescences*, which have arisen in an inflammatory exudation.

" Now here, on the threshold of the subject, a doubt occurs—Is the lining membrane of the arterial system susceptible of inflammation ? ' Inflammation,' in the language of the schools, ' consists in an increased action of the blood-vessels of a part.' Without pledging ourselves for the accuracy of this definition, we may use it in the present instance as a rough criterion of inflammation ; at least negatively. No part can be said to inflame, in the ordinary sense of the word, which has not vessels of its own. You cannot talk of inflammation of the hair or nails. What, then, are the bloodvessels of the lining membrane of the arterial system, which this theory supposes to be the seat of an increased action ? That portion of an artery which we term its inner coat has no bloodvessels of its own, nor do those of the middle or contractile coat (which are derived from the so-called *vasa vasorum*) penetrate to a sufficient depth to influence materially (if at all) the nutrition of the lining membrane.

"In the Museum of the College of Surgeons there is a preparation of Mr. Quekett's (an injection done, as all Mr. Quekett's are, with admirable success), which shows how very much the *vasa vasorum* fall short of reaching the lining membrane of the artery. And—if you will but think for a moment, what should *vasa vasorum* do there? what could they convey more fit for the nutrition and growth of the membrane than what is already there?—than that blood, namely, which is already washing over it incessantly and profusely.

"And again, gentlemen, reflect on this: the lining membrane of the artery and of the valves has an epithelium; wherever epithelium grows, the old cells drop off in a direction opposite to that whence the new ones derive their materials of growth. Just as our scales of epidermis drop from the surface of our bodies, being nourished and renewed from within; just so, if the epithelium of an artery were renewed from without (i. e. by *vasa vasorum*), the old scales, as fast as they became detached, would drop into the interior of the vessel; and though, no doubt, their decay is very slight, and the number that might thus pass into the circulation, and presently obstruct the capillaries, would be very small, still it would be essentially a clumsy arrangement.

"From a variety of reasons, it seems almost certain that the ordinary nutrition of the lining membrane of the circulating system is derived directly from the blood with which it has contact; and that its morbid changes depend—not on any inflammatory condition due to the *vasa vasorum*, but on those humoral changes, those variations in the qualities of the blood, by which it is more immediately and more certainly affected than any tissue of the body.

"On these grounds there would be great *primâ facie* difficulty in believing that the endocardial deposits could be of inflammatory origin. But this is not all; for, if they were inflammatory exudations, why should they be so peculiarly limited to projecting or uneven surfaces of the lining membrane? And why should they evince so decided a preference for the *left* side of the heart? Both sides of the heart, and all points of each cavity, are (one would think) equally exposed to the causes of inflammation; the coronary arteries supply both ventricles of the heart indifferently, and we well know that acute *peri*-carditis pays no respect to the grooves and septum of the heart; it traverses all such lines of demarcation, injects the bloodvessels of right and left side alike, and covers ventricles and auricles equally with its dense inflammatory exudation. On the supposition that these vegetations are inflammatory effusions from the membrane, I should be quite unable to explain why they should almost entirely confine themselves, as they do, to the valvular apparatus; and why their predilection for the left side should be so great, that the right is very rarely affected—perhaps never, except where the left has first suffered, and where the disease has been of such extreme intensity, that even its weaker affinity for the right side has been able to manifest itself.

"The opposite doctrine is the more tenable one. I believe that the origin of these vegetations is directly humoral; that they arise as fibrinous precipitations from an overcharged solution; the valves encrusting themselves with fibrin, just as a stick in certain streams coats itself with a calcareous envelope; and that the preference shown for the left side of the heart admits of explanation by reference to the peculiarities of its contents—the new-made arterial blood.

"You will observe that this theory involves the supposition, that arterial blood is more prone than venous blood to precipitate its fibrin, either as containing more of it, or as containing it in some more separable form.

"Not wishing to leave this a matter of uncertainty, I have experimented on the subject. I have carried a single thread, by means of a very fine needle, transversely through the artery and vein of a dog, leaving it there so

that it might cut the stream ; and I have done this repeatedly, sometimes in the femoral vessels, sometimes with the carotid and jugular, sometimes with the aorta and cava. I have suffered the thread to remain during a period of from twelve to twenty-four hours. My experiments have given me as a uniform result, that the arterial blood with the utmost readiness deposits its fibrin on the thread ; the venous blood with the utmost reluctancy. And in most of my experiments, the thread, where it traversed the canal of the artery, presented a very considerable vegetation on its surface (exactly like those we are talking of on the valves of the heart) ; a vegetation sometimes as large as a grain of wheat ; always of a pyramidal shape, with its apex down-stream, and its base attached to the thread. In the artery, one might say that the thread whipped the blood, just as one whips blood in a basin to get the fibrin out of it ; but with this trifling difference, that, instead of the rod beating the fluid, the fluid ran over the rod and precipitated its fibrin there. In the vein, the thread seemed to operate no way but obstructively ; never coating itself with fibrin, but sometimes delaying or stopping the circulation with a voluminous black clot, chiefly collected on that side of the thread remotest from the heart. Accordingly, the general statement and rationale of the matter appears to be as follows :—the disease in which these deposits are so frequent is one of intense over-fibrination of the blood, and one in which almost certainly there are other conditions, besides *quantity*, making the fibrin easy of precipitation ; the left side of the heart has preference, because it is the arterial side, and because arterial blood, as we have seen, readily parts with its fibrin ; the valves, and particularly their streamward surfaces, are chosen for the deposit, because their position exposes them chiefly to the friction of the current ; so that the whole curious selection of site for the deposit resolves itself into the concurrence of two conditions, which are fulfilled in that one spot of the vascular system—namely, the greatest chemical tendency to the deposition of fibrin, with the greatest mechanical facilities for its entanglement.

" In introducing this subject, I mentioned that it is one of great practical importance. Many people bleed locally, or even generally, when they hear an endocardial murmur arising in the course of rheumatic fever. In their eyes, the new disease is endocarditis ; and everything ending in *-itis* is thought, in at least a majority of instances, to be benefited by bleeding. Therefore, gentlemen, do not be in a hurry to call it endocarditis ; and, as for bleeding, all that I would venture to say (for of course the treatment of this physician's disease does not fall within my province) is, to assure you of the pathological fact, that you may bleed a patient to death without altering (except probably to increase) the proportion of fibrin in his blood.

" I may mention, however, as of some pathological interest, that in a recent work on Diseases of the Joints, by a French surgeon of considerable experience (M. Bonnet of Lyons), a section is devoted to the treatment of acute rheumatism by nitrate of potass in large doses (up to an ounce or an ounce and a half per diem). He speaks of its utility in the highest terms, and he quotes with full concurrence a passage from M. Gendrin, who has likewise used the medicine very extensively, to the remarkable effect that this method of treatment possesses this among other advantages, that it prevents inflammation of the endocardium,—*il prévient les endocardites.* You will find an interesting paper, on the same method of treatment, communicated by Dr. Basham to the Medico-Chirurgical Society, and published in the last volume of their *Transactions.*

" Now we know that nitrate of potash is a powerful solvent of fibrin ; we know that in these large doses a quantity of it must be retained in the blood, and we are thus enabled to interpret the efficiency of the remedy in accordance with our knowledge of the disease. Nitre, if present in the blood in sufficient quantities, would prevent fibrinous concretions on the valves, by increasing the solubility of this material, and diminishing its liability to precipitation." (pp. 54-58.)

The subject discussed in the Fourth and Fifth Lectures is DERANGEMENTS IN THE QUANTITATIVE DISTRIBUTION OF THE BLOOD. *Hyperæmia* may be either passive or active. Passive hyperæmia results from mechanical causes impeding the return of blood from a part. The vessels are too full of blood, but of blood which has been already fully used, and is therefore not in a fit condition to minister to nutrition; accordingly there is no over-growth consequent upon the repletion. But effusion very constantly results, and often gives rise to serious mischief. The fluid thus poured out is the *liquor sanguinis*, generally more or less deprived of its nutritive ingredients, the fibrin and albumen.

Active Hyperæmia is a very different process. It is not produced by mechanical impediments to the return of blood, but by causes which attract that fluid in undue quantities to any particular part. Mr. Simon regards molecular changes in the tissues as the primary step, and brings forward strong reasons for demurring to the opinion that an impression on the sentient nerves must precede the changes. Among other reasons, he adduces the following case, which we quote as being remarkably conclusive.

"A patient had complete anæsthesia of the fifth nerve, dependent (as a *post-mortem* examination subsequently showed) on its organic disease; the conjunctiva, as well as the integument of the face, was utterly insensible; not only was the function of the nerve destroyed, but those reflected nutritive changes of which I have already spoken had taken place, and had exhausted themselves; showing that the nerve was spoilt for participation in the acts of nutrition (whatever they may be), no less than for its more obvious uses as a medium of conscious sensation: the cornea had undergone ulceration, and had healed again. The following experiment was carefully made. The lids being held open, a single granule of cayenne pepper was laid upon the insensible conjunctiva; in a few moments it had become the centre of a very distinct circle of increased vascularity, the redness of which slowly became more and more distinct as long as the stimulus was suffered to remain; so that, on its removal, there was a very evident circumscribed erythema on the surface of the membrane. I consider myself justified in believing that this change occurred without any intermediate nervous excitement; not only because the history of the case would lead me to consider the fifth nerve as annihilated; not only because the experiment was totally unattended with sensation, but likewise because there was the very remarkable absence of that sympathetic phenomenon, which the faintest remnant of nervous excitability would have produced—namely, there was not the slightest trace of lacrymation." (p. 76.)

But these molecular changes probably, in most instances, produce an impression on the nervous centres, from which, by a reflex action on the middle muscular coat of the arteries, relaxation of the vessels results, and thus an increased quantity of blood is conveyed to the part. If this increased supply can be all used by the tissues in their healthy workings, hypertrophy of the organ is produced. If the supply be greater than what can be thus employed, new products are evolved—cells or fibres, foreign to the healthy structure of the part. In this we have the distinction between hypertrophy and inflammation; their general pathology has much in common; their causes are often alike—their modes of production identical. But in hypertrophy, however large may be the supply of blood, it all goes to the true nourishment of the organ, goes to increase the number of its natural molecules; while, in inflammation, all that is redundant goes to the formation of new products.

Atrophy is the converse of this. There is less blood than natural in the part; and this diminished supply may either be caused by mechanical impediments to the current, or result from the want of attraction of the tissues themselves, as is seen in organs long unused. Both these conditions, hypertrophy and atrophy, are illustrated by numerous examples.

The Sixth Lecture is occupied with the PRODUCTS OF INFLAMMATION. It is full of interest, and will well repay perusal, but is scarcely susceptible of analysis within moderate limits. In speaking of fibrinous effusions, Mr. Simon again dwells upon his peculiar views of the nature of that substance, and expresses his doubts of its tendency to become organised, believing that the instances generally adduced in proof are merely examples of the organisation of albumen, the true nutritive blastema which had been entangled in the meshes of coagulated fibrin. He regards suppuration as the natural end of inflammation, and considers that it is only to be avoided by arresting the progress of the inflammatory action, and thus preventing the completion of the natural steps. He believes that the new vessels which are found in inflammatory effusions, when they become fully organised, are prolongations of the vessels of the old tissues, not real new formations.

The Seventh and Eighth Lectures treat of TUMOURS. Mr. Simon first gives a general, and very graphic description of them, under the several heads of tegumentary, vascular, fatty, fibrous, cartilaginous, bony, cystic, and cancerous. He then, in a very interesting recapitulation, distributes them into four groups. 1. *Tumours by accumulated secretion*, such as encysted tumours of the scalp, simple ovarian cysts, bronchocele, etc. 2. *Hypertrophic tumours*, including the tegumentary and fatty, which are illustrations of partial hypertrophy, and the bony, as nodes and exostosis, which result from what he denominates adjunctive hypertrophy. 3. *Hypertrophic tumours with conversion of tissue*, as cartilaginous tumours connected with bones, or fibrous tumours of bones or cartilages. 4. *Eliminative tumours*, which include all the varieties of cancer. As the author's view of the nature of cancer is by no means common, we quote his reasons from the original.

"Finally, gentlemen, the difficult task remains to me of setting before you the pathological affinities and contrasts of *Cancer*. Let me remind you that I use the word generically; including under it the three species of which I have spoken, and taking the encephaloid form as its most perfect and characteristic illustration.

"Fix your attention, first of all, on the total unlikeness of cancer to any kind of tumour we have hitherto considered: observe how impossible it is to regard cancerous growths as accumulated secretion of any organ in which they arise, or as the results of its hypertrophy, either interstitial or adjunctive. They are distinctly new products—new developments of the organism; and they correspond to some new purpose. The evolution of a cancerous tumour in the body marks, I apprehend, a new state of things in respect of the patient's total organisation and vitality; just as much as the first acting of the kidneys in the embryo, and of the lungs in the infant, respectively mark new eras in the animal's progressive development.

"Thrust aside all the accidents and trivialities of the subject; strip the question naked; and what does a cancer mean? Substantially it is a new excretory organ. Under the pressure of some mysterious constitutional necessity, a growth arises, which (in its typical form) tends essentially to acts of eliminative secretion; just as distinctly as the healthy liver or the healthy kidney. You must not stop short at the *tumour*: you must scan the whole drama of the disease, in which the tumour forms but a pro-œmium. Look again at such a case as I gave you for illustration—a case of encephaloid manifested in the globe of the eye: that vast fungating ulcer which ensues on the protrusion of the tumour, and which continues hourly to purge forth its profuse discharge,—that is the real intention and purpose of the tumour, as palpably as urine expresses the intention of the kidney, or bile the intention of the liver. The cells of the tumour have grown like healthy gland-cells—like the nucleated cells of a mucous membrane, only to discharge themselves with their contents. There is nothing, I repeat, like hypertrophy in the disease: it consists essentially in the establishment of a new vent—a new organ of elimination; and that organ develops itself according to the

type of other secreting organs; it develops itself as an apparatus for the formation of deciduous cells.

"How constitutional—how intensely constitutional—is this eliminative action, can hardly be misunderstood. The mere fact that Nature thus (if I may say so) deliberately, and without any exterior provocation, organises in one spot of the body a drain which becomes so ample as to starve the remainder; the circumstance that this flux is not a single emptying out of some previous local accumulation (such as one sees in the pointing and discharge of an abscess) but is a persistent process, depending day by day on new acts of growth; the observation that the tendency to the disease is in many instances hereditary; the existence of a marked cachectical state which precedes, as well as accompanies, the evolution of the tumour; and, most of all, that flagrant evidence of metastasis[1] which daily renews itself for our instruction, consisting in the failure of surgical operations, by reason of the obstinate emergence of the disease, even again and again, in parts previously uncontaminated by its presence:—these arguments are to my mind as conclusive for the constitutional and purely constitutional origin of cancer, as any which I could adduce to show you the constitutionality of small-pox or gout.

"Thus much is beyond question. And, while I tell you that a cancerous tumour is an organisation for excretory purposes, I wish I could go further, and could explain to you what is that mysterious condition of system in which this eliminative effort has its root; what it is that enables and induces the blood thus to starve those various organs which are the natural claimants of its substance, and thus to waste itself in works of supererogation. We have seen parasites acting thus by the body; we have seen the blood involuntarily yielding up its richness to their extraneous suction. But here the case is quite different; the blood seems (if I may use the phrase) spontaneously and voluntarily, and under no pressure of local circumstances, to set about constructing an organ for the appropriation and discharge of its own blastema. It is from sedulous chemical investigations alone, that we can hope for light on this most difficult subject: from such investigations, I mean, as will compare the total chemistry of the cancerous body—blood, tumour, excretions—with the total chemistry of the healthy body; and especially will found themselves on an exact and comprehensive knowledge of those natural changes which occur in the progressive and regressive metamorphoses of the blastema of the blood. Hitherto the chemists have done nothing for us in respect of this disease; and till they have furnished us with the information just indicated, our hopes of cure must necessarily

[1] "I am content to rest my justification of the word "metastasis", on the habitual return of the disease after operations, even when they have been performed with the best apparent prospect of success. But a case is quoted, on the authority of Parent-Duchatelet, which looks more like what is generally recognised as *metastasis*, namely, that the disease spontaneously deserts one site, and simultaneously addicts itself to another. As a solitary instance, it adds little or nothing to the evidence of surgical practice; but I transcribe the case for its curiosity:—'A woman,—after having suffered for a length of time from a tumour in the breast, which possessed all the characters of non-ulcerated scirrhus, and after having presented the symptoms of cancerous cachexia in so marked a manner, that Dupuytren not only refused to remove the diseased organ, but dissuaded Parent-Duchatelet from the use of leeches,—was seized with remittent cephalalgia of intolerable violence; at the same the mammary growth ceased to be painful, and eventually disappeared almost completely. Apoplectic symptoms, with hemiplegia, supervened, were combated with the ordinary means, and recurred twice before the patient's death, which took place ten weeks after the first apoplectic seizure, and two years after the supervention of the symptoms in the breast. On *post-mortem* examination, a tumour of the size of a nut, and possessing (according to Cruveilhier) the characters of carcinoma, was discovered floating, as it were, in a quantity of diffluent brain.'"

remain dormant, or must content themselves with speculative and empirical endeavours. For pathology distinctly traces a chemical function in the disease, and shows that it is from the basis of chemistry alone that any rational cure of the disease may possibly be argued out.

"In the ground we have gone over, you will have seen what it is which constitutes the so-called *malignity* of cancer, and which assigns it a separate place and a higher importance in the list of morbid growths; this, namely, —that the cancerous tumour is a mere symptom of constitutional disease, a mere phenomenon locally arising in a concentrated act of the entire system, as demonstrably and as simply as a paroxysm of gout is the local product and local evidence of a general disorder." (pp. 152-155.)

Scrofula is the subject of the Ninth Lecture. Mr. Simon very strongly, and we think rightly, insists upon the fact, that tubercle is the essential and diagnostic product of scrofula. He believes it to be strictly hereditary, and very difficult of artificial production. He does not absolutely deny that it may be so produced, but shows that it is much more rarely so done than is generally imagined, and that many of the recorded experiments are fallacious.

"Having spoken of experiments performed on the lower animals, I feel bound to caution you against a too implicit belief of all you may read in books as to the experimental production of tubercle. Statements on this subject have been made and disseminated too hastily. For instance, rabbits are cited by authors, as peculiarly prone to become subjects of the disease. 'A rabbit, fed in a damp, dark cellar, on watery vegetable food (says Mr. Phillips), soon becomes the victim of tubercular deposits.' There are certain influences (says Dr. Walshe) 'which experience has proved to lead unfailingly to the development of tubercle in the liver of rabbits.' Four or five years ago, when I was busy with experiments on this subject, I received from a friend the so-called tubercular liver of a rabbit; the deposit was white, not very firm in any part, and in some spots diffluent; it extended in several directions throughout the thickness of the organ, reaching its surface, and bulging it at various points; but there was something in its appearance which struck me at first sight as unlike tubercular deposit; it appeared continuous in lines, rather than in masses; it seemed to branch, too, in the direction of the ducts, as though it were dependent on their anatomical arrangement. I proceeded to examine it with a high power of the microscope, and found, to my astonishment, that the whole mass consisted of the minute oblong eggs of some entozoon. The fact seemed likely to be of importance, and consequently I followed up the observation by others. On inquiry of a *candid* poulterer (for the sellers of eatable stock are naturally reluctant to admit the possibility of disease in their animals) I found that these 'tubercular' livers are common—very common; that they will be found often in almost every tame rabbit cut open, and in litter after litter; and, strangely enough, that they do not appear incompatible with good health, or at least with health sufficiently good for market purposes. Now, I examined dozens of these livers, always with the same result; and I may mention to you, as of some interest in relation to the habits of the entozoon, that while engaged in these examinations, I found the same ova in the gall-bladder and in the whole length of the intestinal canal; in several parts of the latter (as *e.g.* in the cæcum) I observed them actually following the inflexions of the mucous membrane, and lining its follicles almost like an epithelium.

"In continuation I made various experiments, to see if I could produce tubercle artificially, and various other examinations to see if I could find it in rabbits dying under other circumstances. The result may be told in a word: I have never seen tubercle in a rabbit. I do not wish you to infer from this, that rabbits are insusceptible of the disease; my knowledge by no means extends to this; there may have been some share of accident in my non-observation of tubercle among so many specimens; and other more for-

tunate observers may have witnessed the disease, perhaps frequently. But what I would insist on is, that the artificial producibility of tubercular deposit is by no means the simple and straightforward process it is supposed to be. So far as the belief in it depends on such statements as I have cited to you, I feel bound to caution you against its reception ; and I would even venture to say, that at the present moment the balance of evidence is against the supposition that tubercle can be produced in animals by any of the means which I have specified.

"For I may inform you in addition, that, not only in rabbits, but in sheep, and in cats or dogs which have been made the subjects of experiment, a very large proportion (I refrain from saying *all*) of the alleged tubercular deposits, artificially produced, prove, on careful examination, either to be instances of parasitic development in the substance of the lungs, or to consist of some other morbid product utterly unlike human tubercle." (pp. 166-168.)

Our author's general views are thus summed up. "The material products of the scrofulous diathesis consist in some mis-developed proteinous ingredient of the lymph and blood. The essence of this mis-development lies in the fibriniform solidification and concretion of something which should remain fluid in the plasma of the blood. I call it *fibriniform*, because—though it is not identical with fibrin, it probably arises in some analogous method of formation, and undergoes similar final metamorphoses. This solidification occurs in the ascensive development of the lymph and blood : it occurs with an infinite preference in the lymph-glands and in the lungs ; in the former, where lymph is brought into intimate relations with arterial blood ; in the latter, where lymph (which is constantly accruing to the blood) first comes into immediate relations with the atmosphere. It seems then to affect the total blood, only by reason of the lymph which is contained in it ; in other words, not to be a disease of the total blood, but one of the lymph or nascent blood. Precipitability by the atmosphere is the characteristic of this morbid product ; its places of election are determined by this peculiarity : tubercles form, where lymph and blood get their first opportunities of increased oxidation. In accordance with this law, venosity of the blood precludes the tendency to tubercular deposition. The fibriniform product of scrofula is insusceptible of development : it is a dead concretion. Like true fibrin, it may become the seat of calcareous deposit, and may thus form a permanent inorganic concretion. Like true fibrin, it chiefly tends to soften, and its softened substance is copiously infiltrated with fat : probably it undergoes a fatty degeneration. The diathesis in which tubercular deposits occur, is accompanied by a remarkable tendency to the accumulation of fat in the liver, and to the fatty degeneration—either of the substance of other organs, or of some previous infiltration in those organs : possibly this tendency may indicate that the fibriniform material of tubercle in its molecular state can undergo, either in the blood, or in those organs, the same degenerative changes as affect it in its concrete condition. In short, the scrofulous diathesis consists in an inherited peculiarity of blood-development, under the influence of which the nascent blood tends to a molecular death by super-oxidation ; partly it may appear that these dead proteinous elements can undergo, within the stream of the circulation, such degenerative changes as will qualify them for discharge by excreting organs ; partly it may appear that these changes lead to fatty accumulations in the endothelium or in the parenchymatous blastema of such organs ; but mainly and characteristically, it is the way of those dead proteinous elements to concrete in the organs where their precipitation has been determined, and there to construct the fibriniform masses called *tubercle*. These masses undergo changes of deliquescence and destruction, which tend to their ultimate expulsion from the system, but which, as they entail the disorganisation of all surrounding textures by inflammatory and ulcerative processes, are commonly defeated in this tendency when they occur in vital organs (as the lung) or attain it

by the complete sacrifice of the invaded organ, as when present in lymph-glands, testicle, or breast.

"I have told you that cancer and tubercle are incompatible diseases—that the one excludes the other. You cannot wonder at this. They are pathological antitheses in regard of the blood. In the one case, if I may use so strong a phrase, the blood dies still-born; it never attains its maturity of growth or function; it stops short of the distributive arteries of the body; it never reaches the aorta; it perishes and decays on the threshold of the circulation. In the contrary case of cancer, there is an obstinate excess of vitality, which will not be quenched. You remember how the blood's plasma, as though out of a luxuriance of life, contributed—not to perishable concretions, but to profuse living growths; you remember how these growths, tending to an effort of elimination, still maintained an interrupted dependence on the blood, constituting the strange paradox of an organised excretion; you remember how they evolved themselves with exhaustive rapidity out of a too fructifying blastema, vegetating without limit at the expense of other organs, till the whole fluid of the circulation seems to devote itself, away from its slower and legitimate uses, to this impetuous by-play of organisation." (pp. 185-187.)

The Pathology of the Nervous System forms the subject of the Tenth Lecture, which is one of the most interesting and valuable of the whole. We must, however, content ourselves with this simple statement, for condensation would only spoil what is already quite full of matter, and a mere selection of parts would give no right idea of the whole.

The Eleventh Lecture is occupied with the subject of Evacuative Medicines in Relation to Humoral Pathology, and exhibits a melancholy, and, we cannot but think, somewhat overdrawn picture of the deficiencies of our knowledge of therapeutics, and of our impotence as respects the treatment of humoral diseases. We are deeply sensible of the great necessity which exists for more complete and more exact inquiries into the actions of medicinal agents, and agree with Mr. Simon in thinking, that full chemical examination of the blood and the excretions in health, in disease, and under the operation of particular remedies, is the right method for arriving at satisfactory conclusions. But we think more has been already done than he gives us credit for, and were surprised to find no reference whatever to the investigations of Mialhe, or to the very valuable observations of Dr. Golding Bird, on what he has denominated chemical diuretics.

The last Lecture treats of Morbid Poisons, and is undoubtedly one of the most interesting of the whole. After showing the general characteristics of these poisons, and their distinction from ordinary poisons, and illustrating their operation by the phenomena of continued fever and small-pox, he enters into the following explanation, which appears to us to give about the clearest idea of the events that we have met with anywhere.

"We have it accordingly demonstrated, that for the production of the disease there must be a *specific internal*, as well as a *specific external* condition; that the former is liable to be exhausted; and as it becomes exhausted in the production of material phenomena (namely, in the generation of pustules), therefore, obviously, it must itself be a *something material*, like that outward condition with which it cooperates; as the *poison of small-pox* is a something material and tangible, so the *susceptibility to small-pox* is a something material and tangible. Of this material—whatever it may be—no trace remains in the blood, when the disease has completed its course.

"Thus we get a general formula for the pathology of small-pox, which will be useful as a standard of comparison for the other poisons in our list. A certain organic material, A, soluble and partially volatile, affects particular relations with B, an ingredient (apparently a normal ingredient) of the blood: the result of their coming together are (1) the utter destruction of the latter, B; and (2) the immense increase of the former, A; not indeed at

the spot of infection, but elsewhere. On the one hand, the *virus* augments so much that it is found all over the body, forming innumerable pustules, and contaminating the breath with its volatile miasma ; on the other hand, the inward natural *ingredient of the blood* simultaneously diminishes, and at the end of the process is found totally exhausted.

" Look at this as a chemical experiment : you add A to B ; presently you find that B has vanished, and that A has undergone an immense augmentation. What is the meaning of this ? What has become of B ? Whence has the new A been derived ? It is difficult to avoid the conviction, which arises with almost logical certainty, that the increase of one material, and the decrease of the other, have stood in essential mutual relation ; that, in short, it has been a process of *conversion ;* that the essential relation of the two matters (that derived from *without,* and that contained *within* the blood) has consisted in the ready convertibility of one into the other ; that the specific power of the virus is its power of effecting this transformation, and no other.

" Finally, that material of the blood in which the virus of small-pox effects this peculiar change, seems, though a *normal* constituent, to be no *essential* one ; for the patient convalescent from small-pox, though with no demonstrable trace of that constituent in his blood, returns to at least as good health as he ever enjoyed previously. It may be added, too, that in a certain very small proportion of persons this natural ingredient of the blood appears to be not *uniformly* present ; for there are persons (apparently undefended by any previous occurrence of the disease, or by other known means) in whom your original inoculation would have failed ; persons, who would have shown a non-infectibility by the poison, and who therefore must (at least, for the time) have been without that material in their blood which constitutes the susceptibility to the disease." (pp. 263-4.)

The modified severity of attacks produced by inoculation is thus accounted for. " I may take this opportunity of explaining to you a difficulty which arises in the doctrine of morbid poisons, from considering the mitigation which their severity often appears to undergo, when they are infected by artificial inoculation. It appears, that while infection is the certain test and evidence of certain materials in the blood, inoculation is, in many cases, a much finer test than can be afforded by atmospheric inhalation ; and, as the severity of symptoms will be in proportion to that chemical state of the individual by which he is infectible, so I would explain the frequent comparative mildness of inoculated small-pox. By inhalation of the volatile virus, fewer would be affected, but those few would have the disease severely ; this method of infection including only those persons who possess a great abundance of the material which renders infection possible, and who (by reason of their large possession of that material which leads to the production of symptoms) would naturally suffer much ; while the process of inoculation (being, as I expressed it, a finer test) will elicit evidence of the disease from a far larger number of persons, will include many who possess a minimum of the symptom-producing material, and who, for that very reason, will suffer the disease in its mildest form. On the same principle, I would explain that other fact, well known in practice, that on the first invasion of an epidemic, the proportional mortality is greatest ; while later in its progress (when far larger numbers are attacked), the proportion of recovery is increased. At the commencement of the epidemic, the exterior causative influence is at its minimum : those only contract the disease at this period who possess, in an extreme degree, that interior condition which constitutes the specific susceptibility, and which (as I have already explained) measures the severity of an attack in exact proportion to the facility with which it is incurred." (pp. 267-8.)

Mr. Simon reviews at considerable length the two great theories of infection—*contagium animatum* and *fermentation*, and rejects both. His own views may be in part gathered from the following summary.

"Therefore, gentlemen, as respects those instances of human morbid infection with which we are best acquainted, we may recapitulate our facts, and state our theory, in the following terms: that certain materials of the blood —materials not essential to the performance of its nutritive functions—are, by certain circumstances, rendered liable to undergo definite and specific changes; under the influence of which they become determined, with increased rapidity, to the outlets of the body, and irritate these outlets in their passage; that these changes continue, until the materials affected by them are completely exhausted from the blood; and that the severity and duration of those changes is in proportion to the quantity of material seeking elimination: that the new matters engendered and evolved under these circumstances are capable, in various ways, and with more or less certainty, of producing a precisely similar succession of changes in the blood of another individual, or of any number of individuals; operating always on the same ingredients of the blood as that whence themselves arose, and determining it to the same outlets as that whither themselves were determined; so that the choice of material in the blood, and the choice of outlet in the body, constitute specific characters for the several morbid poisons distinctively, and so that the final products act always as special catalytics for that original material of the blood, wheresoever they may encounter it. But, finally, that under certain possible conditions of accumulation, or tension, in that original material, other circumstances may serve to start it in its progress of specific decomposition, without any demonstrable influence from that exterior catalytic, which is the ordinary occasion of its change." (pp. 285-6.)

We have thus concluded our task, which has been a very pleasant one; and in taking leave of the volume we heartily thank Mr. Simon for the instruction he has communicated to us in a form so agreeable, and strongly advise our readers to peruse the original for themselves.

Action of the Muscular Coat of the Bronchial Tubes in Respiration. By C. Radclyffe Hall, M.D. pp. 24. Worcester: Deighton and Co. 1850.

The object of this essay is to prove that the views of Reisseisen upon the regular and rhythmical action of the muscular coat of the bronchial tubes during respiration, may be sustained by experiment and by reasoning. The general opinion of physiologists has been against these views; and their objections are stated and combated by Dr. C. R. Hall with great acuteness and ability. His experiments clearly prove that when the vagus nerve in some animals had been divided, regular although rapid contractions of the lungs might be caused by the agency of galvanism applied to that portion of the nerve which descended to the lungs; thus shewing, in opposition to the views of most physiologists, that the bronchial muscular fibres are capable of rhythmical contraction, and that they are under the influence of the nerves. The objection made by Müller, that if the muscular coat of the bronchial tubes acted rhythmically in respiration, it would have to be under the influence of the will, is easily disposed of by Dr. C. R. Hall, who observes that the diaphragm and other respiratory muscles present rhythmical contractions which are not quite independent of the will, and that the heart exhibits rhythmical contractions which are quite independent of the will, and therefore that the more or less subordination of the will cannot be the condition on which rhythmical action depends. Although Dr. C. R. Hall succeeded in producing rhythmical contractions by stimulating the divided vagus nerve in a rabbit and in a fowl, yet in frogs, whose lungs possess no muscular coat, the stimulation of the vagus produced no such effect, but the expanded air-bag emptied itself by the mere force of its elasticity. Hence the author concludes that where there is no muscular coat, there are no rhythmical contractions. Dr. C. R. Hall draws an ingenious analogy between the respiratory

function in the fish and that performed by the mammalia. In the former, there are two distinct acts of respiration, namely, the deglutition of water by the mouth, and its ejection from the gills, and Dr. C. R. Hall suggests that these alternate and rhythmical actions may be effected by the relaxation and contraction of the interbronchial muscle, which is therefore analogous to the bronchial muscle of the mammalia, the act of expelling the water from the gills corresponding to the act of expiration, and the interbronchial muscle operating as an expiratory agent. In the mammalia, it may be presumed that the ordinary exciting cause of inspiration is distention of the capillaries of the lungs with carbonized blood, and the exciting cause of expiration, the presence in the air-cells and bronchial tubes, of unduly carbonized air. The author concludes that although many of the phenomena of respiration may be explained by the elasticity of the bronchial tubes, yet that the alternate acts of inspiration and expiration are regulated by the rhythmical action of the bronchial muscles.

Such is a very imperfect abstract of Dr. C. R. Hall's views. Regretting that our limits do not enable us to follow the author through all his experiments and arguments, we recommend his valuable essay to the careful attention of those who are interested in this branch of physiology.

Scale of Medicines with which Merchant Vessels are to be furnished, by Command of the Privy Council for Trade: with Observations on the means of preserving the Health, and increasing the Comforts of Merchant Seamen; Directions for the Use of the Medicines, and for the Treatment of various Accidents and Diseases. By T. Spencer Wells, F.R.C.S., Surgeon, Royal Navy. pp. 190. London: 1851.

This is an unpretending little volume, written by one thoroughly acquainted with his subject. Mr. Wells has evidently founded his practice upon a considerable amount of experience and observation, as well as upon a judicious study of the best writers. His remarks upon *ventilation* are particularly good. It is distressing to reflect that a very little attention to this subject would have prevented several recent disasters attended with much loss of life, from the immuring of multitudes of people under hatches in bad weather. In treating of *diet*, the author justly prefers meat which is preserved in close vessels to that which is salted; and he also states his opinion that in all large ships, and certainly in all steam-ships, it is quite practicable to convert salt water into water which is fit for human consumption. Some observations are arranged alphabetically upon the accidents and diseases to which seamen are most liable, and a scale of medicines and medical stores is appended. Short practical descriptions are given of the most common forms of disease, and their treatment is also concisely laid down. The doses of medicines, and their mode of administration, are also carefully detailed. In cases where a ship is sent to sea without a medical practitioner on board, this little work will prove extremely useful.

We cannot omit this opportunity of remarking that far too little attention is generally paid in merchant versels, even of the first class, to the selection of efficient medical practitioners; and we have reason to fear that *cheapness* is the chief consideration with owners in making these appointments.

Dr. Hooper's Physician's Vade-mecum; or a Manual of the Principles and Practice of Medicine. By Wm. Augustus Guy, M.B. Cantab. *New Edition.* pp. 576. London; 1851.

This is an improved edition of a deservedly popular work. Students and practitioners will find it a well arranged and trustworthy book of reference. The formulæ are judicious, and are eminently calculated to assist the young prescriber.

LETTER TO THE RIGHT HONOURABLE LORD CAMPBELL, LORD CHIEF JUSTICE OF THE COURT OF QUEEN'S BENCH, ON THE CLAUSE RESPECTING CHLOROFORM IN THE PROPOSED "PREVENTION OF OFFENCES BILL". By JOHN SNOW, M.D.

It is a pity that when legislators set about making laws, they do not take council with competent advisers. Lord Campbell's domains are law and literature; but in the department of toxicology he has assuredly no status; and this Dr. SNOW has seasonably shown in reference to chloroform. We hope that the noble and learned lord will reassure the public, and admit that assaults cannot be facilitated by means of this drug.

The following passages from Dr. Snow's letter (which we regard as a valuable contribution to state-medicine) are interesting and conclusive.

"The prominent mention of chloroform, in the fourth clause of the Bill presented by your lordship to the House of Lords, on the 24th ult., is to be regretted on other grounds. It ill becomes the gravity of the law, and is, I feel assured, far from your lordship's intention, that a legal enactment should be made on a false alarm, or to meet a trivial and unsuccessful innovation in the mode of attempting a crime: to legislate on this matter would revive the groundless fears of the public, which have subsided, or been allayed; and might even cause evil-disposed persons to make trial of a means, which they would conclude to be not without efficiency, when it had given rise to a law for its suppression. There is no reason to believe that chloroform has been employed in more than two instances with criminal intent; and so far from aiding the perpetration of crime, it has led to the immediate detection of the offender, on both occasions. The knowledge of these two cases is more calculated to deter from similar attempts, than any increase of the punishment, which a culprit might expect to escape altogether, by avoiding detection.

"When administered gradually, chloroform can be breathed easily enough, by a person willing and anxious to take it; but he has to draw his breath many times before he becomes unconscious. During all this interval, he has a perfect perception of the impression of the vapour on his nose, mouth, and throat, as well as of other sensations which it causes; and every person who has inhaled chloroform retains a perfect recollection of these impressions and sensations. If chloroform be given to a child whilst asleep, the child awakes, in nearly every instance, before being made insensible, however gently the vapour may be insinuated. No animal, either wild or tame, can be made insensible, without being first secured; the chloroform may, it is true, be suddenly applied on a handkerchief to the nose of an animal, but the creature turns its head aside, or runs away, without breathing any of the vapour. If a handkerchief, wetted with sufficient chloroform to cause insensibility, is suddenly applied close to a person's face, the pungency of the vapour is so great as immediately to interrupt the breathing, and the individual could not inhale it, even if he should wish. From all these facts it is evident that chloroform cannot be given to a person in his sober senses, without his knowledge and full consent, except by main force. It is certain, therefore, that this agent cannot be employed in a public street or thoroughfare; and as the force that would be required to make a person take it against his will, would be more than sufficient to effect a robbery, and enough to effect any other felony by ordinary means, it would afford no help to the criminal in more secluded situations. Supposing that the felon or felons could succeed in keeping a handkerchief closely applied to the face, the person attacked would only begin to breathe the chloroform when thoroughly exhausted by resistance or want of breath, and when, in fact, the culprits could effect their purpose without it. * * * *

"On January 10th, a robbery was committed in Thrall Street, Spitalfields, for which two women, named respectively Elizabeth Smith and Margaret Higgins, were examined three or four times at Worship Street, tried at the

Central Criminal Court on February 8th, convicted, and sentenced to be transported for fifteen years. The following is the evidence given by the prosecutor, at one of the examinations before Mr. Hammill. He was proceeding along the Whitechapel Road, between 9 and 10 o'clock in the evening, 'when he felt some one, whom he believed to be a woman, touch his left side, and at the same time felt a rag or handkerchief pressed over the lower part of his face. He instantly became insensible, and was conscious of nothing that occurred to him, until about day-light the following morning, when he slowly revived, and upon recovering sufficiently, found himself lying in a very dirty bed, in a wretched apartment.' (*Times*, January 25, 1850.) It will be observed by your lordship that the witness gives no account of either the local or general sensations which chloroform causes. He felt a handkerchief or rag applied to his face, and instantly became insensible. This circumstance alone indicates that chloroform was not the agent employed. But there are other reasons which prove the view I entertain of the matter. Whitechapel Road is a very busy thoroughfare between 9 and 10 in the evening; and admitting that a gentleman could be made insensible in the instantaneous manner alleged, without the opportunity of making the least resistance, or calling for assistance, it is impossible that he could be dragged, or otherwise conveyed, in that state to another street, without attracting the attention of passers by, and even causing the collection of such a crowd as would ensure the interference of the police. As the effects of chloroform subside very rapidly when quickly induced, the dose would, moreover, require to be repeated, before the victim could be conveyed a distance of two or three hundred yards. If the transaction occurred at the time and placed alleged, the prosecutor, however insensible he might be, must have appeared to accompany the woman voluntarily; but I know no drug which can be administered on a handkerchief to produce effects of this kind, and am inclined to believe that the agent which could cause such results must be more subtle than anything that can be contained in an apothecary's phial. Whether it was witchcraft, animal magnetism, or some other invisible kind of attraction, I shall not attempt to decide. The long continuance of the insensibility (ten hours) in this case, shows that it was not caused by chloroform, the effects of which pass off in a few minutes, or, at the longest, in half an hour; and this remark applies to every substance that will quickly cause insensibility, when breathed from a handkerchief; for the volatility which enables it to be taken in this way, causes its ready elimination from the blood, in its passage through the lungs. It must be concluded, therefore, that the insensibility, in this instance, was caused by something which had been swallowed. Laudanum, ardent spirits, and fermented liquors, are articles which are capable, amongst others, of causing prolonged stupor, but there are no means of ascertaining now what might have been used. After the examination of the prisoners in this case had been two or three times adjourned, a woman came forward and gave evidence that, on an occasion previous to the robbery, the prisoner Higgins 'had told her that a man named Gallagher, with whom she cohabited, had undergone an operation at the London Hospital, where they had given him some stuff to send him to sleep, and that he had contrived to bring some of it away with him from that institution.' (*Times*, January 25, 1850.) The medical officers of the London Hospital have no knowledge of any chloroform having been taken away by a patient; and it must occur to your lordship that the statement of a person who alleged that she had been in the confidence of the thief, and had kept her unlawful secrets for a long time, carries with it no great weight. Whilst the alleged action of chloroform in the above instance was too instantaneous, in the other case of alleged robbery by means of this agent its reputed action was so long deferred, as to prove clearly that it proceeded from a different cause.

"Charlotte Wilson was tried at the Surrey Adjourned Sessions, on February 9th, 1850, for a robbery committed on a man in the beginning of the

previous month. The prosecutor stated that he was walking along the Borough, towards London Bridge, when he was accosted by the prisoner, who passed a handkerchief across his face, and he became very unwell. Not suspecting that any narcotic was contained in the handkerchief (a circumstance which alone is sufficient to prove that no chloroform was used), he ran into a public-house hard by, and called for a glass of brandy. A police constable stated that he saw the prisoner accost the prosecutor, and pass something across his face. He then saw them enter the public-house, when he saw the woman drinking with the prosecutor. About ten minutes afterwards he saw the prisoner run out of the house with a hat and scarf. The prosecutor was at that time insensible.

"The effects of chloroform are induced whilst a person is breathing it, and attain their greatest intensity within twenty seconds after the inhalation has ceased; it is consequently impossible for a person to go into a public-house, and be seen drinking there, between the time of taking the chloroform and the insensibility induced by it. The man was a considerable time before he recovered his senses; another circumstance which proves that the stupor had not been caused by chloroform. A non-medical witness, who gave evidence before the magistrate, was confident that the stupor or insensibility was not caused by liquor, but by some deleterious article such as chloroform. The court and jury who tried the prisoner were of the same opinion, and she was sentenced to be transported for ten years, although a student from any hospital in London could have informed the court that chloroform had not been employed. The landlord of the public-house in which the robbery was committed, said that the prosecutor appeared to be in liquor when he entered. This evidence may be safely received; for a publican could not be deficient in experience on this point, and could hardly be influenced by prejudices that would lead him to consider a customer intoxicated who was not so. This evidence being admitted, the case is perfectly clear; for nothing is more common, when a person in liquor goes on drinking, than for him shortly afterwards to be lying insensible. * * *

"On April 30, 1850, a young man, named Charles Jopling, was placed at the bar, before Mr. Broughton, at the Marylebone Police Court, charged with having attempted to administer chloroform, with intent to violate a young woman, to whom he had been paying his addresses for nine months. It was proved, that whilst returning from a concert at a public-house, about one o'clock the same morning, the prisoner induced the complainant to accompany him down a yard, when he uncorked a phial, poured the contents on a handkerchief, and applied the latter to her face. She immediately pulled away the handkerchief, and called out so loudly that she obtained the assistance of a policeman from the neighbouring street, who took her assailant into custody. When asked by the magistrate if she felt any ill effect from the application of the handkerchief, the complainant replied as follows: 'I did not, your worship, as I pulled it away from my face instantly; it was completely saturated with wet, and had a remarkably strong smell.' The prisoner was remanded, and bail was accepted for his appearance on a future day. During this interval he married the young woman, and at the next examination she begged for his discharge. After a further remand, and a severe lecture, the worthy magistrate reluctantly surrendered the prisoner to his wife, who, if she does not remain of the same forgiving disposition, doubtless finds means of punishment as severe as any which the law had in store for him.

"In October last, a man named Charles Venn contrived to secrete himself under a bed, in an hotel at Kendal, and attempted to give chloroform, at midnight, to an elderly gentleman in his sleep. The effect of this attempt was to awake the gentleman; and although the robber used such violence that the night-dress of his victim was covered with blood, and the bedding fell on the floor in the scuffle, he did not succeed in his purpose. The people

in the house were disturbed, and he was taken into custody, and ultimately sentenced, at the Westmoreland Michaelmas Sessions, to eighteen months' imprisonment with hard labour, including one month's solitary confinement.

"A crime was committed in France on a person under the influence of chloroform, but not by the agency of that article. The chloroform was voluntarily inhaled by a female, for the lawful purpose of having a tooth drawn without pain, and the dentist took advantage of the stupor so induced, as he might have done of a fainting fit, or any other kind of insensibility, to effect violation.

"I trust that I have said sufficient to induce your lordship to consider whether it would not be advisable to withdraw the word chloroform, the presence of which can only be alarming to the public, suggestive to the criminal, and little creditable to the sagacity and gravity of the law; whilst its removal would not affect the operation of the act, even in a case, should such a one again occur, in which it might be foolishly attempted to exhibit the article.

"In conclusion, I will venture to make a few additional remarks on the operation of the fourth clause of the bill presented by your lordship.[1] All the dietetic and medicinal, as well as other narcotics, are capable of causing stupor when taken in sufficient quantity. The stupifying or overpowering matters in most frequent use in this country, are ardent spirits, wine, and beer. I conclude that the clause under consideration does not apply to spirituous and fermented liquors, when openly given, with whatever intent, but to the fraudulent administration of other substances, similar in action, but more powerful. It cannot be denied that opiates are sometimes exhibited, with felonious intent, in malt liquor, the bitterness of which disguises their taste, and such a crime cannot be too severely punished; but it would be a great error to conclude that the offence called *hocussing* is so common as the statements of prosecutors at the police courts would imply. Persons who have been dead drunk are very unwilling to admit, even to themselves, that the result was the consequence of their own voluntary potations, and still less willing to admit it to the world, when they have to complain of having been robbed whilst in bad company. Therefore, before such evidence is received as conclusive, it should be confirmed by chemical analysis, or in some other way; otherwise errors may occur, such as that at the Surrey adjourned sessions, alluded to above.

"The rapid supervention of stupor ought not to be accepted as proof that it was not occasioned by spirituous or fermented liquors, for these articles sometimes produce their effects with great velocity. Ardent spirits, indeed, under some circumstances, act with greater rapidity than almost any thing else except prussic acid, and on some occasions are not even surpassed by that poison. * * *

"At the trial of Johannah Driscoll at the Central Criminal Court in December last, for a robbery committed in a house of ill fame, it was alleged that chloroform might have been put into some gin taken by the prosecutor. Chloroform, however, although very soluble in rectified spirit of wine, does not mix easily with potable spirits, and when dissolved imparts to them such a very hot and sweet taste, that no one could take them without being aware of the adulteration."

---

[1] The clause runs as follows. "And whereas it is expedient to make further provision for the punishment of persons using chloroform or other stupifying things, in order the better to enable them to commit felonies: be it enacted, that if any person shall unlawfully apply or administer, to any other person, any chloroform, laudanum, or other stupifying or overpowering drug, matter, or thing, with intent thereby to enable such offender, or any other person, to commit any felony upon the person to whom the same may be applied or administered, or attempted to be applied or administered, or upon his or upon any other person's property, every such offender shall be guilty of felony, and being convicted thereof shall be liable, at the discretion of the court, to be transported for life, or for any term not less than seven years."

A Letter to the Right Hon. Sir George Grey, Bart., M.P., on some of the Social Relations of the Medical Profession. By George Robinson, M.D., Newcastle-upon-Tyne. pp. 28. London: 1850.

This pamphlet is written with some ability, and sets out with a profession of candour and impartiality; but, in the first few pages, the author has manifested such an utter ignorance of the condition of the general practitioners of this country, and of their relation to the different licensing boards, that we think it unnecessary to comment upon the statements he brings forward, or the plans of reform which he advocates. If Dr. Robinson had consulted the evidence, which is open to him and to all, upon the extensive strides which the general practitioners of this country have made since 1815, he would not have written so much that is absolutely inapplicable to the present state of the profession. He has represented that the Apothecaries' Act, of 1815, has degraded medicine to a trade! The effect of it has been precisely the reverse, for it has elevated a trade to a profession. The course of events, and the increasing spread of intelligence, may have rendered the Act inapplicable to the practitioners of the present day; but if the legislature should repeal it, they will no doubt substitute some other measure of equal, or of greater efficiency. In the meantime, good medical legislation is not likely to be forwarded by the publication of such essays as that of Dr. Robinson; in which the past and not the present state of the profession is made the basis of the proposed reform.

Pharmacopœia ad Usum Nosocomii Phthisicorum et Pectoris Morbis Ægrotantium accommodata. Editio secunda. pp. 42. Lond. 1851.

This is a very admirable collection of formulæ for the administration of medicines in the different stages, and for the relief of the various urgent symptoms which occur in phthisis and other diseases of the chest. Like the report which emanated[1] from the conjoined physicians of the Brompton Hospital, it bears the stamp of sound science and excellent practice. It ought, however, rather to be considered as a selection from the most commonly used prescriptions of the physicians of the hospital, than as a codex of simple or elementary formulæ equally calculated to assist the labour of the dispenser, and to prevent the prescriber from wholly falling into the routine exhibition of complex formulæ, the exact composition of which he may often fail to bear in mind. As hospital officinal preparations, the formulæ ought perhaps to have been simpler, more scope being left for each prescriber to adapt them by additions to the specialities of each case.

An example will best illustrate our meaning. Among the Misturæ, we find the following.

Mistura Strychniæ. ℞ Strychniæ semigranum, Acidi nitrici diluti fluidrachmam dimidiam, Acidi hydrocyanici diluti fluidrachmam, Misturæ camphoræ fluiduncias sex. Fiat mistura. Dosis ʒij ad ʒss.

In place of the above, we would prefer the following.

Mistura Strychniæ Nitratis. ℞ Strychniæ semigranum, Acidi nitrici diluti fluidrachmam dimidiam, Aquæ fluiduncias sex. Fiat mistura.

The mixture ought obviously to be called by its correct name; and as we presume it is chiefly used in the Brompton Hospital as a remedy for vomiting, the camphor mixture ought not to form a constant ingredient; for camphor is very disagreeable to some patients, and not very uncommonly creates nausea and vomiting: then, the prussic acid ought either to be acknowledged in the name of the mixture, or omitted as an ingredient, because it is a medicine at least as efficacious in allaying vomiting as the nitrate of strychnia. It is far better for each prescriber to add the prussic acid when he pleases; for the giving the two invariably in combination is quite unnecessary, and must effectually prevent a correct opinion being formed of the cases in which one or the other is specially useful. Pupils hearing the "Mistura Strychniæ"

[1] For a copious abstract of this Report, see London Journal of Medicine, for January 1850.

ordered, and observing the vomiting cured by it, might never think of turning up the pharmacopœia, and there learning that the relief might depend upon the hydrocyanic acid, and not on the strychnia.

The INHALATIONES require amendment. In the first place, the simplest and best method of *dry inhalation* is in the form of cigarettes. The substance (be it opium, conium, cannabis, etc., having been reduced to powder) is mixed with some mild and suitable substance, and then formed by the little machines (which may be had for a few pence in the Lowther Arcade) into cigarettes. Patients can easily be taught to draw the smoke into the lungs, and slowly expire it, as some amateurs treat the cherished fumes of "a mild Havannah". Medicinal cigarettes (following the formulæ of Dorvault, etc.), might, with very great advantage, be introduced into the Brompton Pharmacopœia. In *moist inhalation* there ought, we think, to be a large body of aqueous vapour, otherwise the inhalation is performed with difficulty; the vapour only rising in abundance when excessive heat is applied. The following formula is calculated to bring a valuable medicine into discredit.

INHALATIO CREASOTI. Creasoti minima sex, Aquæ fluiduncium dimidium. Inhaletur vapor (caloris ope) ex vase idoneo.

We have extensively prescribed creasote inhalations, and can testify to their signal utility in a vast number of cases. They promote expectoration, diminish excessive secretion in the air-tubes and from the interior cavities, remove fœtor when it exists, and have a general soothing influence. The creasote when inhaled must, however, to be of any use, be taken into the lungs without effort, and by inhaling freely, from a large-mouthed vessel, the steam of *creasote water*. Altogether, creasote is too little considered at Brompton. We would recommend the introduction of the creasote mixture of the *Edinburgh Pharmacopœia*, and also a mixture with mucilage. A creasote pill with crumb of bread would likewise often be useful. When the nitrate of strychnia and hydrocyanic acid do not remove sickness, creasote, in one or other of these forms, will rarely fail to give relief. When patients are taking the coarser kinds of cod-liver oil, the administration of a dose of creasote mixture, half an hour before each dose of the oil, will generally enable a squeamish stomach to retain it; it will also be a valuable therapeutic adjunct to the oil in many cases.

There are only two formulæ for ENEMATA—the "Enema Catharticum" and the "Enema Opii". An enema of acetate of lead, another of nitrate of silver, and another of logwood are wanted; for in the diarrhœa of phthisis they are all invaluable; and in some cases, they may each in turn be required.

The only SOLUTIO is the following:—

SOLUTIO IODINII CAUSTICA. ℞ Iodinii, Potassii iodidi, singulorum unciam, Spiritûs rectificati fluiduncias duas. Solve.

A much milder solution of iodine is sometimes wanted as a daily application to the chest. The subjoined is a good formula: or the above may be diluted.

SOLUTIO IODINII MITIS. ℞ Iodinii et Potassii Iodidi, singulorum drachmas duas, Liquoris potassæ drachmas tres. Aquæ fluiduncias duas. Fiat solutio ope penicilli applicanda.

The only UNGUENTUM is the following:—

UNGUENTUM ANTIMONII POTASSIO-TARTRATIS. ℞ Antimonii potassio-tartratis drachmam, Adipis purificati drachmas tres. M. F. unguentum.

For most cases, this is too violent: but the prescriber can easily, *pro re natâ*, direct more lard to be added. To make a proper ointment, free from grittiness, the salt ought to be dissolved in a few drops of water before it is mixed with the lard; and the addition of this, as a direction to the apothecary, would improve the formula.

From the tenor of our remarks it may be inferred, that it is easier to criticise a good Pharmacopœia than to compile even an indifferent one. No book of this class, we believe, can be made to suit the notions of every practitioner; but there are few well-informed readers who will not derive practical hints from the perusal of the little work before us.

ALPHABETICAL CATALOGUE

Of the Papers which have appeared in the French Medical Journals for 1850.

BY ALEXANDER HENRY, M.D.

THE following are the Journals referred to in this Catalogue, with the abbreviations used.

Bulletin de l'Académie Nationale de Médecine ...	Bull. de l'Acad. de Méd.
Comptes Rendus de l'Académie des Sciences ...	Compt. Rend.
Archives Générales de Médecine	Arch. Gén. de Méd.
Bulletin Général de Thérapeutique	Bull. Gén. de Thér.
Gazette Médicale	Gaz. Méd.
——— des Hôpitaux	Gaz. des Hôp.
L'Union Médicale	Union Méd.
Annales d'Oculistique	Ann. d'Ocul.
——— Médico-Psychologiques	Ann. Méd.-Psych.
——— d'Hygiène Publique	Ann. d'Hyg. Pub.

ABDOMEN, Phlegmon of Anterior Wall of. BERNUTZ (Dr. G.) Arch. Gén. de Méd., June and July 1850, vol. xxiii, 4th S., pp. 129, 290.

ACCIDENTS from Machines in Public Workshops. Ann. d'Hyg. Pub., April 1850, vol. xliii, p. 261.

ACHROMATOPSY, new Observations on. D'HOMBRES FIRMAS (M.) Ann. d'Ocul., March 1850, vol. v, 4th S., p. 127 ; and Compt. Rend., Jan. 28 and April 1, 1850, vol. xxx, pp. 57 and 376.

ADANSONIA DIGITATA, Bark of, in Intermittent Fever. PIERRE (M. Simon). Compt. Rend., July 22, 1850, vol. xxxi, p. 85.

ADENITIS, Cervical: Extirpation of Glands. LARREY (M. H.) Bull. de l'Acad. de Méd., April 16, 1850, vol. xv, p. 619.

ADULTERATION of Food (bread). CHEVALLIER (M. A.) Ann. d'Hyg. Pub., Jan. 1850, vol. xliii, p. 171.

ALBUMEN of Blood and Organic Fluids, Physiological and Pathological Researches on ; with description of an Albuminimeter. BECQUEREL (Dr. A.) Arch. Gén. de Med., Jan. and Feb. 1850, vol. xxii, 4th S., pp. 52, 156.

ALBUMINURIA, connexion of with Amaurosis. CUCUEL (Dr.) Union Med., Jan. 17, 1850, vol. iv, p. 30. ABEILLE (M.) Gaz. des Hôp., Jan. 15, 1850, vol. ii, 3rd S., p. 25. LANDOUZY (M. H.) Union Méd., Oct. 26 and 29, 1850, vol. iv, pp. 522 and 526.

ALCOHOL, Simple Means of Detecting the nature of Substances added to. GAULTIER DE CLAUBRY (M. H.) Ann. d'Hyg. Pub., July 1850, vol. xliv, p. 48.

AMMONIA, Liquid, Internal Use of. TESSIER (Dr. N. B.) Bull. Gén. de Thér., 1850, vol. xxxix, p. 53.

AMPUTATIONS, Celsus's method of Performing. LACAUCHIE (M. A. E.) Gaz. Méd., May 11, June 22 and 29, 1850, vol. v, 3rd S., pp. 360, 377, 467, 487.

ANÆSTHESIA, and Anæsthetic Agents in Surgery. A critical abstract of the works published on the subject. ARAN (Dr. F. A.) Arch. Gén. de Méd., March 1850, vol. xxii, 4th S., p. 308 ; Nov., vol. xxiv, p. 314. Local. ARAN (Dr. F. A.) Bull. de l'Acad. de Méd., Nov. 19, 1850, vol. xvi, p. 114. Local, by means of Freezing Mixture. VELPEAU (M.) Union Méd., April 6, 1850, vol. iv, p. 169.

ANEURISM, Treatment of, by Galvano-Puncture. BOSSÉ (M. C.) Gaz. Méd., Aug. 17, 1850, vol. v, 3rd S., p. 610. Of Ductus Arteriosus. THORE (M. Jun.) Arch. Gén. de Méd., May 1850, vol. xxiii, 4th S., p. 30. Of Subclavian Artery, successfully treated by Electro-puncture. ABEILLE (M.) Bull. de l'Acad. de Méd., April 9, 1850, vol. xv, p. 572. Arterio-venous. ROUX (M.) *Ibid*, Nov. 26, 1850, p. 127.

Angina Tonsillaris, Treatment of, by Emetic Doses of Tartarised Antimony, without bleeding. Bourgeois (Dr.) Arch. Gén. de Méd., August 1850, vol. xxiii, 4th S., p. 436.

Ankylosis, Rupture of; Subcutaneous Section. Bonnet (M.) Gaz. Méd., May 25, June 1, 15, July 6 and 13, 1850, vol. v, 3rd S., pp. 395, 414, 449, 505, and 527. Philipeaux (M.) Bull. Gén. de Thér., 1850, vol. xxxix, p. 442.

Antimonial Powder, remarks on Employment of. Papillaud (Dr. L.) Gaz. Méd., Oct. 26, 1850, vol. v, 3rd S., p. 775.

Aphonia, Treatment of by Alum. Saucerotte (Dr.) Bull. Gén. de Thér., 1850, vol. xxxviii, p. 360.

Apoplexy, Rachidian. Gendrin (M.) Gaz. des Hôp., April 20 and 27, 1850, vol. ii, 3rd S., pp. 191 and 203.

Arm-presentations, Practical Observations on. Géry (Dr. L. H.) Bull. Gén. de Thér., 1850, vol. xxxix, p. 397.

Arsenic in Skin-diseases and Intermittent Fevers. Gibert (Dr.) Bull. Gén. de Thér., 1850, vol. xxxviii, pp. 193, 289, 439; vol. xxxix, pp. 103, 197, 251. Granules a preferable form for Administration of. Guillarmand (M.) *Ibid.*, 1850, vol. xxxix, p. 405. Cases of Poisoning by. Ann. d'Hyg. Pub., April 1850, vol. xliii, p. 420; Oct. 1850, vol. xliv, p. 433.

Arteries, Cases of Wounds of. Baudens (M.) Gaz. des Hôp., March 5, 1850, vol. ii, 3rd S., p. 109. Cicatrisation of, after Ligature: Secondary Hæmorrhage, and its Treatment. Notta (M. A. H.) Gaz. Méd., Dec. 7, 21, and 28, 1850, vol. v, 3rd S., pp. 870, 899, and 912. Of Hand (palmar arch), Forceps for arresting Hæmorrhage from. Galiay (Dr.) Bull. Gén. de Thér., 1850, vol. xxxix, p. 73.

Arteritis, Cl. Lect. on. Gendrin (M.) Gaz. des Hôp., July 30, Aug. 6 and 29, Sept. 12, 19, and 25, 1850, vol. ii, 3rd S., pp. 357, 370, 405, 429, 442, and 453.

Artificial Pupil, Formation of at the time of Operating for Cataract. Tavignot (Dr.) Gaz. Méd., Aug. 24, 1850, vol. v, 3rd S., p. 623.

Ascites, Treatment of, by Iodine Injections. Leriche (Dr.) Union Méd., February 7, 9, 12, 1850, vol. iv, pp. 65, 69, and 73. By Oily Inunction. Venturini (Dr.) Bull. Gén. de Thér., 1850, vol. xxxix, p. 32. Umbilical Paracentesis in: Production of Epiplocele. Forget (M.) *Ibid.*, 1850, vol. xxxviii, p. 481.

Assassination of Countess of Görlitz: Spontaneous Combustion. Tardieu and Rota (MM.) Ann. d'Hyg. Pub., July and October 1850, vol. xliv, pp. 191 and 363.

Atmospheric Pressure in relation to Respiration, Hæmatosis, and Capillary Circulation. Pravaz (Dr.) Bull. de l'Acad. de Méd., March 19, 1850, vol. xv, p. 520.

Atrophy, Progressive Muscular. Aran (Dr. F. A.) Arch. Gén. de Méd., Sept. and Oct. 1850, vol. xxiv, pp. 5 and 172.

Biogenic Law. Barbier (M. J. B. G.) Gaz. Méd., Nov. 30, 1850, vol. v, 3rd S., p. 850.

Bismuth, Trisnitrate of, in Large Doses. Monneret (M.) Bull. Gén. de Thér., 1850, vol. xxxviii, p. 433.

Bladder, Paralysis of, Treated by Electricity. Michon (M.) Bull. Gén. de Thér., 1850, vol. xxxviii, p. 348. Bonin (M. J.) *Ibid.*, 1850, vol. xxxix, p. 505. Neck of, Treatment of Diseases of. Civiale (M.) Gaz. des Hôp., April 6, 1850, vol. ii, 3rd S., p. 165.

Blood, Analysis of. Verdeil (M. F.), and Dollfus (M.) Compt. Rend., May 27, 1850, vol. xxx, p. 657. Researches on White Corpuscles in. Davaine (Dr.) Gaz. Méd., Dec. 7, 1850, vol. v, 3rd S., p. 884. Diminution of Fibrin in, by Running. Hervier (M. P.) *Ibid.*, March 30,

1850, vol. v, 3rd S., p. 243. Anæmia and Dropsy from diminution of Albumen in. Becquerel and Rodier (MM.) *Ibid.*, April 13, 1850, vol. v, 3rd S., p. 277. Human, Researches on Alkalinity of Serum of. Cahen (Dr., Junr.) Bull. de l'Acad. de Méd., July 2, 1850, vol. xv, p. 933.

Brain, Diseases of, Cl. Lect. on. Rostan (M.) Gaz. des Hôp., June 11, 15, and 22, 1850, vol. ii, 3rd S., pp. 274, 281, and 294. Relation of Symptoms to. Forget (M.) Union Méd., July 27, 1850, vol. iv, p. 366. Congestion of, Essay on. Bouchet (M.) Ann. Méd.-Psych., April 1850, vol. ii, p. 161. Tissue of, dried, medico-legal Researches on. Orfila (M.) Bull. de l'Acad. de Méd., June 25, 1850, vol. xv, p. 873; and Ann. d'Hyg. Pub., July 1850, vol. xxiv, p. 143.

Bronchocele, Extirpation of a. Roux (M.) Bull. de l'Acad. de Méd., Sept. 3, 1850, vol. xv, p. 1106.

Burns, Local Treatment of. Hervez de Chégoin (M.) Union Méd., August 13, 15, 17, 20, 31, and Sept. 2, 1850, vol. iv, pp. 394, 398, 401, 405, 426, and 429. General Treatment of. Hervez de Chégoin (M.) *Ibid.*, Nov. 19, 1850, vol. iv, p. 559.

Cæsarean Section, Case of. Beneys (Dr.) Bull. Gén. de Thér., 1850, vol. xxxviii, p. 545.

Cafeine and its Preparations. Dorvault (M.) Bull. Gén. de Thér., 1850, vol. xxxviii, p. 498. Citrate of, in Migraine. Hannon (Dr. J. D.) Union Méd., June 4, 1850, vol. iv, p. 270.

Calculi, Biliary, Diagnosis and Treatment of. Fauconneau-Dufresne (Dr.) Union Méd., Jan. 10, 1850, vol. iv, p. 18.

Calculus, Large Urinary, in a Woman, expelled Spontaneously. Forget (M.) *Ibid.*, Sept. 28, 1850, vol. iv, p. 473.

Cantharides, Ethereal Solution of. Œttinger (M.) Bull. Gén. de Thér. 1850, vol. xxxix, p. 261. Abs. in Lond. Journ. of Med., Nov. 1850, vol. ii, p. 1037.

——— Powdered, Detection of Adulteration of. Stanislas Martin (M.) *Ibid.*, 1850, vol. xxxviii, p. 35.

Carbon, Vegetable, in Idiopathic and Sympathetic Gastro-Intestinal Nervous Affections. Belloc (M.) Bull. Gén. de Thér., 1850, vol. xxxviii, pp. 54 and 204. Entrance of, and of other insoluble matters, into circulation. Œsterlen (M.) Gaz. des Hôp., Aug. 13, 1850, vol. ii, 3rd S., p. 383.

Cataract, slow Restoration of Sight after Operation of Depression for. Gosselin, (Dr. L.) Arch. Gén. de Méd., June, 1850, vol. xxiii, 4th S., p. 156. Black; its Diagnosis. Beauclair (M. A.) and Pétrequin (M. J. E.) Ann. d'Ocul., March 1850, vol. v, 4th S., p. 130. Abs. in Lond. Journ. of Med., Aug. 1850, vol. ii, p. 799. From Lightning. Rivaud-Landreau (Dr.) Union Méd., April 27, 1850, vol. iv, p. 205.

Chest, Sulphureous Waters of Enghien in Diseases of. Bolland (Dr.) Gaz. Méd., Feb. 2, 1850, vol. v, 3rd S., p. 87. Effusions in, especially Chronic. Gendrin (M.) Gaz. des Hôp., May 7 and 18, 1850, vol. ii, 3rd S., pp. 217 and 234.

Chloroform in Midwifery; Cases and Observations. Chailly-Honoré (Dr.) Union Méd., Feb. 21, 1850, vol. iv, p. 89. In Cutaneous Diseases and certain Nervous Affections. Devergie (M.) Bull. Gén. de Thér., 1850, vol. xxxviii, p. 345. Febrifuge and anti-periodic Properties of. Delioux (Dr. J.) Arch. Gén. de Méd., May 1850, vol. xxiii, 4th S., p. 51. Most frequent Cause of Accidents from Inhalation of. Angelon (M.) Compt. Rend., Jan. 7, 1850, vol. xxx, p. 5. Oxygen as an Antidote to Poisoning by. Duroy (M.) Union Méd., May 7, 1850, vol. iv, p. 221.

Chlorosis and its Treatment. Bull. Gén. de Thér., 1850, vol. xxxviii, p. 145.
Cholera in the Public Institutions of Paris in 1832 and 1849. Blondel (M.) (Analysed by Dr. Aran.) Union Méd., Oct. 26, Nov. 9, 1850, vol. iv, pp. 521, 541. Epidemic; Infection. Pellarin (Dr.) Bull. de l'Acad. de Méd., July 30, 1850, vol. xv, p. 988. Report of Commission on. Guérin (M. J.) *Ibid.*, July 30, 1850, vol. xv, p. 1023. Influence of Locality, Water, and Habitation, on Development of, in the South of France in 1834 and 1835. Fourcault (M.) Gaz. Méd., May 18 and June 1, 1850, vol. v, 3rd S., pp. 373 and 411. Influence of, on other Diseases. Limousin (M.) Bull. de l'Acad. de Méd., June 18, 1850, vol. xv, p. 860. Cholera and Accouchement, reciprocal Influence of. Devilliers (Dr. Jun). *Ibid.*, July 16, 1850, vol. xv, p. 967. Nervous Affections following. Burq (M. V.) Gaz. Méd., Feb. 2, 1850, vol. v, 3rd S., p. 82. Pathology of, especially with regard to Lungs. Walther, (Dr. A.) Arch. Gén. de Méd., Oct. 1850, vol. xxiv, 4th S., p. 162. Treatment of, by the Method of Priessnitz. Wertheim (Dr.) Bull. Gén. de Thér., 1850, vol. xxxix, p. 439. Exanthemata connected with. Thore (Dr., Jun.) Gaz. Méd., June 29, 1850, vol. v, 3rd S., p. 484.
Chorda Tympani, Electro-Physiological and Pathological Researches on. Duchenne (Dr.) Arch. Gén. de Méd., Dec. 1850, vol. xxiv, 4th S., p. 385.
Chorea, Sulphate of Strychnine in. Trousseau and Lacaze du Thiers (MM.) Union Méd., Feb. 14 and 19, 1850, vol. iv, pp. 78 and 86. Treatment of, by Friction with Chloroform. Gassier (Dr. L.) Bull. Gén. de Thér., 1850, vol. xxxix, p. 174.
Cod-Liver Oil, Pharmacological Remarks on. Dorvault (M.) Bull. Gén. de Thér., 1850, vol. xxxix, p. 360. In certain Chronic Affections. Escallier (Dr.) Union Méd., Jan. 19 and 22, 1850, vol. iv, pp. 33 & 38.
Colic, Nervous, Alum in. Philipeaux (M. E. R.) Bull. Gén. de Thér., 1850, vol. xxxix, p. 485.
Collodion, Occlusion of Eyelids by. Hairion (Dr. F.) Ann. d'Ocul. July, Aug. and Sept. 1850, vol. vi, 4th S., p. 124. For producing artificial Ectropeon. Cunier (Dr. F.) *Ibid.*, Oct. 1850, p. 186.
Constipation from Abuse of Purgatives. Guéneau de Mussy (Dr. N.) and Aran (Dr. F. A.) Union Méd., Feb. 16 and 19, 1850, vol. iv, pp. 82, 85.
Convulsions, Puerperal; in what Cases ought Delivery to be hastened? Pingault (M.) Union Méd., Sept. 7 and 14, 1850, vol. iv, pp. 437 and 448. In Connexion with Renal Disease; Case. *Ibid.*, August 29, 1850, vol. iv, p. 421. Blot (Dr. H.) *Ibid.*, Oct. 10, p. 493. Abs. in Lond. Journ. of Med., Nov. 1850, vol. ii, p. 1082.
———— in Children, Clinical Researches on. Ozanam. Arch. Gén. de Méd., March 1850, vol. xxii, 4th S., p. 257; May and June, vol. xxiii, pp. 5 and 163.
Copper, Workmen in. Chevallier and Boys de Loury (MM.) Ann. d'Hyg. Pub., April 1850, vol. xliii, p. 337; July 1850, vol. xliv, p. 27.
Cornea, Ramollissement of, in Consumptive Diseases. Hubsch (Dr.) Ann. d'Ocul., Jan. and Feb. 1850, vol. v, 4th S., p. 101. Cauterisation of, Abuse of. Deval (M. Charles). Union Méd., May 16, 1850, vol. iv, p. 238.
Coryza, abortive Treatment of, by Vapour of Acetic Acid. Saint-Martin (Dr.) Bull. Gén. de Thér., 1850, vol. xxxviii, p. 409.
Cough; its Treatment. Gendrin (M.) Gaz. des Hôp., March 23, 1850, vol. ii, 3rd S., p. 143.
Craniomalacia in Children. Laségue (Dr.) Arch. Gén. de Méd., Feb. 1850, vol. xxii, 4th S., p. 187.
Cretinism, Examination of the Report of Sardinian Commission on. Brierre de Boismont (M. A.) Ann. Méd. Psych., April 1850, vol. ii, p. 205; July, p. 393. Boudin (M.) Arch. Gén. de Méd., Sept. 1850, vol. xxiv, 4th S., p. 65.

Croup, Tracheotomy in, three successful Cases of. Dépéret-Muret (Dr.) and Boulland (Dr. C.) Union Méd., August 3 and 6, 1850, vol. iv, pp. 377 and 381.

Crystalline Lens, traumatic Dislocation of. Rivaud-Landreau (M.) Ann. d'Ocul., July, Aug. and Sept., 1850, vol. vi, 4th S., p. 72. Sub-conjunctival Dislocation of. Barbier (Dr.) *Ibid.*, p. 83.

Curare, Researches on. Bernard and Pelouze (MM.) Union Méd., Oct. 17, 1850, vol. iv, p. 505.

Cystitis, Chronic; Case. Mordret (M.) Bull. de l'Acad. de Méd., Aug. 13, 1850, vol. xv, p. 1052.

Death, Apparent, in New-born Children. Cazeaux (M.) Gaz. Méd., April 27, 1850, vol. v, 3rd S., p. 316.

Delivery, Researches on, with regard to Rupture of the Membranes. Devilliers (Dr., Jun.) Bull. de l'Acad. de Méd., July 2, 1850, vol. xv, p. 929. At the Homes of the Women, necessity of, shewn by the Physiological and Pathological Conditions of New-born Children. Loir (Dr.) and Royer Collard (M.) *Ibid.*, April 2, 1850, vol. xv, p. 554.

Dentifrices, Liquid, superior to Solid. Foy (M. F.) Bull. Gén. de Thér., 1850, vol. xxxviii, p. 221.

Deodorizing Processes. Gaultier de Claubry (M.) Ann. d'Hyg. Pub., Jan. 1850, vol. xliii, p. 77.

Diabetes Mellitus. Bouchardat (M.) Bull. de l'Acad. de Méd., March 26, 1850, vol. xv, p. 538. Rayer (M.) Union Méd., April 11, 1850, vol. iv, pp. 177 and 181. Successfully treated by hydrotherapy. Brachet (M.) Gaz. des Hôp., Oct. 19, 1850, vol. ii, 3rd S., p. 494.

Digitaline. Homolle and Quevenne (MM.) Bull. de l'Acad. de Méd., Jan. 8, 1850, vol. xv, p. 332.

Digiti Semi-mortui, note on. Gillet de Grandmont (M.) Gaz. Méd., May 25, 1850, vol. v, 3rd S., p. 400. Abs. in Lond. Journ. of Med., July 1850, vol. ii, p. 698.

Diphtheritis, Observations on, deduced from an Epidemic observed at the Necker Hospital in 1848. Empis (M. G. S.) Arch. Gén. de Méd., Feb. and March 1850, vol. xxii, 3rd S., pp. 129 and 281.

Disarticulation of Hip-joint, successful case of. Henot (Dr.) Bull. de l'Acad. de Méd., July 30, 1850, vol. xv., p. 1004.

Dislocation of Pieces of Sternum on each other. Chevance (M.) Union Méd., Jan. 3, 1850, vol. iv, p. 6. Of Thigh and Arm, best means of Reducing. Lebert (Dr.) Bull. Gén. de Thér., 1850, vol. xxxviii, p. 177. Complete of Astralagus. Chabanon (Dr.) Gaz. des Hôp., Jan. 3, 1850, vol. ii, 3rd S., p. 5.

Doctrine of Morbid Elements applied to Therapeutics. Forget (M.) Bull. Gén. de Thér., 1850, vol. xxxviii, p. 11.

Drowning or Asphyxia, aid to be given in. Guérard (M. A.) Ann. d'Hyg. Pub., Oct. 1850, vol. xliv, p. 271.

Dysentery, Epidemic at Mortagne; its relation to Cholera. Hullin (Dr. P.) Bull. de l'Acad. de Méd., July 2, 1850, vol. xv, p. 923.

Dyspepsia, Observations on. Chomel (M.) Union Méd., March 7 and 9, and April 2, 1850, vol. iv, pp. 117, 122 and 162.

Elephantiasis, Examination of Hand and Arm of a patient affected with. Rayer and Davaine (MM.) Gaz. Méd., Aug. 31, 1850, vol. v, 2rd S., p. 636.

Ennui, or Tædium Vitæ. Brierre de Boismont (M. A.) Ann. Méd.-Psych., Oct. 1850, vol. ii, p. 545.

Epidemics of the Middle Ages (600 to 1300). De Merssemann (M.) Gaz. Méd., Feb. 16, 1850, vol. v., 3rd S., p. 123.

Epispastics, Lecture on. Gendrin (M.) Gaz. des Hôp., Oct. 3, 1850, vol. ii, 3rd S., p. 465.

Erection, Physiological Examination of the Mechanism of. Debrou (M. E.) Gaz. Méd., Sept. 28 and Oct. 5, 1850, vol. v, 3rd S., pp. 698 and 729.

Ergot of Rye, Influence of on Life of Child and Health of Mother. Danyau (M.) Bull. de l'Acad. de Méd., Oct. 1, 1850, vol. xvi, p. 6 ; also Bull. Gén. de Thér., 1850, vol. xxxix, p. 304.

Ether, Hydriodic, Physiological properties of. Huette (Dr. C.) Gaz. Méd., July 27, 1850, vol. v, 3rd S., p. 568. Abs. in Lond. Journ. of Med., Nov. 1850, vol. ii, p. 1086. Preparation of. Stanislas Martin (M.) Bull. Gén. de Ther., 1850, vol. xxxix, p. 173.

Eyes, and their Appendages, Congenital Malformations of. Cornaz (M. E.) Ann. d'Ocul., Jan. and Feb. 1850, vol. v, 4th S., p. 24. Effusions of Blood in. Tavignot (M.) Gaz. des Hôp., July 9 and 16, 1850, vol. ii, 3rd S., pp. 322 and 334. Cancer of ; Extirpation ; Microscopic examination. Boens (M.) Ann. d'Ocul., July, Aug. and Sept. 1850, vol. vi, 4th S., p. 39. Extract of Cannabis Indica in Diseases of. Binard (M. F.) *Ibid.*, Jan. and Feb. 1850, vol. v, 4th S., p. 99.

Fever, Eruptive, Epidemic of in Brussels. Mareska (M.) Gaz. Méd., Oct. 26, 1850, vol. v, 3rd S., p. 781.

——— Intermittent, Practical Observations on. Nonat (M.) Gaz. des Hôp., March 28 and April 16, 1850, vol. ii, 3rd S., p. 149 and 181. In Africa. Dutroulau (M.) Gaz. Méd., Nov. 2, 1850, vol. v, 3rd S., p. 792. In New-born Children. Guiet (Dr.) *Ibid.*, July 27, 1850, vol. v., 3rd S. p. 564. Common (sea) salt in. Piorry (M.) Bull. de l'Acad. de Méd., Sept. 17, 1850, vol. xv., p. 1122. Comparative value of Arsenic and Quinine in. Maillot (Dr.) *Ibid.*, Sept. 17, 1850, vol. xv, p. 1123. Arsenic in. Mazière (Dr P.) Bull. Gén. de Thér., 1850, vol. xxxviii, p. 36. Vaulpré (Dr.) *Ibid.*, 1850, vol. xxxix, p. 265. Jacquot (M. F.) Gaz. Med., Oct. 12 and Dec. 14, 1850, vol. v, 3rd S., pp. 757 and 885. Treatment by application of Cupping-glasses during the attack. Gondret (Dr.) Bull. de l'Acad. de Méd., May 7, 1850, vol. xv, p. 688.

——— Typhoid, Example of Contagion of. Bouillod (Dr.) Bull. Gén. de Thér., 1850, vol. xxxix, p. 407. Treatment of. *Ibid.*, 1850, vol. xxxix, pp. 246 and 345. Treatment of, by Black Sulphuret of Mercury, and Friction with Mercurial Ointment. Becquerel (M.) Gaz. Méd., Sept. 14, 1850, vol. v, 3rd S., p. 672. Ice to Abdomen and Head in. Bull. Gén. de Thér., 1850, vol. xxxix, p. 35.

——— Typhus, in Silesia. Lasègue (Dr. C.) Arch. Gén. de Méd., July 1850, vol. xxiii, 4th S., p. 301.

Fingers, Separation of Congenital Union of. Didot (Dr. A.) Union Méd., June 18, 1850, vol. iv, p. 295. Nodosities of Flexor Tendons of. Notta (Dr. A.) Arch. Gén. de Méd., Oct. 1850, vol. xxiv, 4th S., p. 142.

Fistula, Vesico-vaginal, Plastic Operation for ; with Cases and Remarks. Jobert de Lamballe (M.) Gaz. des Hôp., March 21, 1850, vol. ii, 3rd S., p. 137 ; also Union Méd., March 28, April 9, May 9, 11, and 14, 1850, vol. iv, pp. 154, 174, 225, 230, and 234. Vesico-uterine and Vesico-utero-vaginal, Curability of. Jobert de Lamballe (M.) Union Méd., Nov. 26, 28, 30, Dec. 3, 1850, vol. iv, pp. 572, 575, 579, and 584. Recto-vaginal ; Cure. Jobert de Lamballe (M.) *Ibid.*, July 18, 1850, vol. iv, p. 349.

Fœtus in Utero, Influence of Bleeding on Development of ; Utility of this Process in certain cases of Narrow Pelvis. Depaul (Dr.) Union Méd., Jan. 12, 1850, vol. iv, p. 22.

Forceps and Cephalotribe, Observations on Application of above Upper Inlet of Pelvis. Chailly-Honoré (M.) Bull. Gén. de Thér., 1850, vol. xxxix, p. 493.

Foreign Bodies in Œsophagus, Indications for Treatment of. Bull. Gén. de Thér., 1850, vol. xxxix, p. 115.

Fracture of Petrous Portion of Temporal Bone. Dronsart (M.) Bull. de l'Acad. de Méd., July 16, 1850, vol. xv, p. 974. Of Inferior Maxilla, Treatment of. Suzeau (Dr. E.) Bull. Gén. de Thér., 1850, vol. xxxviii, p. 70. Longitudinal, of Long Bones. Bouisson (M.) Union Méd., Sept. 19, 21, 24, and 26, 1850, vol. iv, pp. 457, 461, 465, and 469. Of Lower End of the Radius, Treatment of: Method of Professor Bonnet. Philipeaux (M. E. R.) Bull. Gén. de Thér., 1850, vol. xxxviii, p. 207. Of Border of Acetabulum. Bardinet (Dr.) Union Méd., May 25 and 28, 1850, vol. iv, pp. 253 and 258. Of Neck and Body of Femur, New Method of Treating. Martin (M. F.) *Ibid.*, Dec. 14, 17, and 19, 1850, vol. iv, pp. 604, 608, and 611. Of Leg, Apparatus for Treatment of. Gaillard (M. L.) Gaz. Méd., April 6, 1850, vol. v, 3rd S., p. 260. Longitudinal, of Lower Part of Tibia. Célérier (Dr. L.) Union Méd., Oct. 22, 1850, vol. iv, p. 514.

French Army in Africa, Diseases of. Maillot (M.) Gaz. Méd., Jan. 5, 1850, vol. v, 3rd S., p. 2.

Galvanism, Local. Duchenne (Dr.) Arch. Gén. de Méd., July and August 1850, vol. xxiii, 4th S., pp. 257 and 420. In Treatment of Various Diseases. Duchenne (Dr.) Union Méd., March 26, 1850, vol. iv, p. 150.

Gamboge in Large Doses. Abeille (M.) Gaz. des Hôp., March 2 and July 9, 1850, vol. ii, 3rd S., pp. 107 and 321.

Gelatine as an Aliment. Chevallier, Gibert, and Bérard (MM.) Bull. de l'Acad. de Méd., Jan. 22, 1850, vol. xv, p. 367.

Glottis, Œdema of, treated by Scarification. Valleix (M.) Bull. Gén. de Thér, 1850, vol. xxxix, p. 15.

Glycerine, Preparation of. Bull. Gén. de Thér., 1850, vol. xxxviii, p. 219.

Gold, Chemical and Pharmaceutical View of Preparations of. Legrand (Dr. A.) Gaz. Méd., Nov. 9 and 16, 1850, vol. v, 3rd S., pp. 809 and 822. Pharmacological Observations on Preparations of. Bull. Gén. de Thér., 1850, vol. xxxix, p. 450.

Gutta-Percha, Surgical Instruments made of. Cabirol (M.) Bull. de l'Acad. de Méd., July 30, 1850, vol. xv, p. 994.

Hæmometers, Memoir on. Guettet (M.) Gaz. des Hôp., Feb. 23, 1850, vol. ii, 3rd S., p. 95.

Hæmorrhage, Consecutive Arterial, Treatment of. Nélaton (M.) Bull. de l'Acad. de Méd., July 9, 1850, vol. xv, p. 961. Cerebral, Cl. Lect. on. Rostan (M.) Gaz. des Hôp., July 31, Aug. 6 and 20, Sept. 3, 14, and 19, 1850, vol. ii, 3rd S., pp. 361, 371, 389, 413, 434, 441. After Delivery, Observations on. *Ibid.*, April 23 and 25, 1850, vol. ii, 3rd S., pp. 193 and 197.

Hæmorrhoidal Affections, Contraction of Sphincter Ani in. Le Pelletier (M. L.) Union Méd., May 18 and 21, 1850, vol. iv, pp. 242 and 247.

Hare-Lip, Modification of Operation for. Philippeaux (M. E. R.) Bull. Gén. de Thér., 1850, vol. xxxix, p. 392.

Heart, and Aorta, Development of, during the first 144 Hours of Incubation. Prévost and Lebert (Drs.) Gaz. Méd., Nov. 23, 1850, vol. v, 3rd S., p. 834. Ectopia of, with Eventration of most Organs. Follin (Dr.) Bull. de l'Acad. de Méd., Aug. 20, 1850, vol. xv, p. 1073. Palpation in Diseases of. Gubler (Dr. A.) Union Méd., Oct. 19, 1850, vol. iv, p. 509. Sounds of, Alteration of by Pleural Diseases, and Production of Abnormal Sounds in the Pleural Cavity by the Movements of the Heart. Barth (M.) *Ibid.*, Jan. 1, 1850, vol. iv, p. 1. Valvular Endocarditis, Lect. on. Gendrin (M.) Gaz. des Hôp., July 18 and 25, 1850, vol. ii, 3rd S., pp. 337 and 349.

Hemiplegia of Right Side; Sensation entire; Tubercles in Right Lobe of Cerebellum. Tailhé (M.) Gaz. Méd., April 20, 1850, vol. 5, 3rd S., p. 304.

Hepatic Vein, Inflammation of, after acute Abscess of Liver. Tholozan (Dr.) Gaz. des Hôp., June 25, 1850, vol. ii, 3rd S., p. 297.
Hermaphrodism of Internal Organs in a Sheep. Raciborski (M.) Bull. de l'Acad. de Méd., July 9, 1850, vol. xv, p. 963.
Hernia, Strangulated, followed by Abscess and Expulsion of a Lumbricus. Yvonneau (Dr.) Union Méd., Feb. 14, 1850, vol. iv, p. 79. Inguinal, of Colon on Right Side. Lesauvage (Dr.) Bull. de l'Acad. de Méd., Oct. 1, 1850, vol. xvi, p. 30. Strangulated, treated by Chloroform. Gorlier (M. J.) Union Méd., Feb. 7, 1850, vol. iv, p. 67. New Process for Radical Cure of. Valette (M.) Gaz. des Hôp., Sept. 3, 1850, vol. ii, 3rd S., p. 414.
Hydrocele, New Operation for. D'Avat (M.) Gaz. Méd., Feb. 9 and 16, 1850, vol. v, 3rd S., pp. 104 and 129. Baudens (M.) *Ibid.*, Dec. 21 and 28, 1850, vol. v, 3rd S., pp. 901 and 919.

Identity, Influence of Occupations on Question of. Tardieu (M. A.) Ann. d'Hyg. Pub., Jan. 1850, vol. xliii, p. 131.
Infanticide, Case of Suspected. Orfila (M.) Ann. d'Hyg. Pub., April 1850, vol. xliii, p. 374.
Inflammation, Nature of. Marchal de Calvi (M.) Gaz. des Hôp., June 18, 1850, vol. ii, 3rd S., p. 285.
Insane, new Apparatus for feeding. Belhomme (M.) Bull. de l'Acad. de Méd., April 23, 1850, vol. xv, p. 645.
Insanity, Symptomatology of. Parchappe (M. Max.) Ann. Méd.-Psych., Jan. 1850, vol. ii, p. 1 ; Feb., p. 232. Following Acute Diseases. Thore (Dr., Jun.) *Ibid.*, Oct. 1850, vol. ii, p. 586.
Intestine, Piece of, expelled from Anus, with Diverticula. Valleix (M.) Union Méd., Feb. 2, 1850, vol. iv, p. 57. Marage (Dr.) *Ibid.*, July 18, p. 351.
Iodide of Iron, Preparation of Pills of. Gille and Blancard (MM.) Bull. de l'Acad. de Méd., Aug. 13, 1850, vol. xv, p. 1045. Lecanu (M.) Bull. Gén. de Thér., 1850, vol. xxxix, p. 171.
——— of Potassium, Biscuits and Pills of. Stanislas Martin (M.) *Ibid.*, 1850, vol. xxxix, p. 22.
Iodine, a Chemical, Pharmaceutical, and Medical Monograph on the Preparations of. Dorvault (M.) Gaz. Méd., Jan. 2, March 9, 16, 23, April 6 and 21, 1850, vol. v, 3rd S., pp. 9, 178, 199, 222, 263, 321. (The former portions of this memoir were published in the *Gazette Médicale* for Nov. 17 and 24, December 8, 15, and 29, 1849.) Injections of, in Congestive Abscesses. Fleury (Dr.) Gaz. Méd., Oct. 5, 1850, vol. v, 3rd S., p. 732. Boinet (M.) *Ibid.*, Oct. 12 and Nov. 2, pp. 748 and 795.
Iritis as Symptomatic of the Presence of a Foreign Body in the Eye. Desmarres (Dr.) Ann. d'Ocul., Jan. and Feb. 1850, vol. v, 4th S., p. 3.

CRITICAL DIGEST OF THE BRITISH AND FOREIGN MEDICAL JOURNALS.

PRACTICE OF MEDICINE AND PATHOLOGY.

CASE OF HYDROPHOBIA.

Dr. P. Redfern, of Aberdeen, relates in the *Edinburgh Monthly Journal* for February 1851, a case of hydrophobia, occurring twenty-eight days after the bite of a rabid dog, and terminating in death on the fifth day after the commencement of the symptoms. The patient was a child, two years of age. The post-mortem appearances, conjoined with the most careful microscopical examination, especially of the eighth pair of nerves, failed to detect any structural lesion. But it is not improbable that no structural lesion whatever exists in this and in many other nervous diseases; for it is already shown, that a peculiar force is manifested in animals in the physiological actions of the nervous and muscular systems, and that, though this force resembles electricity, yet it is perfectly distinct from it. It then appears very possible, that an increased or perverted action of such a force, upon the tissues of an animal body, may give rise to the whole phenomena of alarming and destructive diseases, and yet leave their structure without a single evidence of material change.

ACUTE RHEUMATISM, WITH DROPSY OF THE PERICARDIUM, IN A CHILD THREE YEARS OLD.

This case appeared, from the symptoms and post-mortem examination, to have been one of simple dropsy of the pericardium, produced by metastasis from the right lower extremity. Authorities speak of both the remarkable points distinguishing this case, viz., acute rheumatism at so early an age, and passive pericardial effusion without inflammation, as extremely rare. The writer (Mr. W. E. Cooksey) inquires if similar cases have been met with. [*Prov. Med. and Surg. Journ.*, Feb. 5, 1851.]

TREATMENT OF APHONIA BY STIMULANT INHALATION.

In the *Transactions of the American Med. Assoc.*, vol. iii. 1850, p. 135, Dr. Pancoast writes to the following effect.

The form of aphonia, here alluded to, is that following an ordinary cold, without leaving any perceptible organic lesion in the pulmonary apparatus. The voice is reduced to a faint hoarse whisper, distinguishable only at the distance of a few feet; and a continued attempt to talk, though it gives no pain, becomes quickly attended with a feeling of fatigue, as though there were some obstruction to the passage of air through the larynx. In breathing merely, there is little or no difficulty; as the individuals are capable of undergoing considerable exertion without any unusual signs of fatigue. Having had an opportunity, several years ago, of observing the movements of the vocal chords in a person who had attempted suicide, and was left with a cicatrised wound opening into the ventricles of the larynx, Dr. Pancoast watched with great interest the play of these vocal chords, which were fully exposed to view, and was astonished at their frequent, varied, and extensive movements. From the evidence he obtained with regard to their motion, he was led to infer that this form of aphonia arose from a partial paralysis of the intrinsic muscles of the larynx, to be cured by stimulating them to action. His first case occurred eight years ago. The patient was a healthy young country girl; the aphonia had lasted for six months, resisting all treatment. She was made to inhale chlorine, gradually liberated from

chloride of soda or lime, by very dilute hydrochloric acid, in a common glass retort. The inhalation was continued for some minutes, and repeated two or three times a day, according to the degree of irritation produced in the throat and larynx. From the first trial, the patient's voice improved, and in three days had become nearly as strong as ever. Two months after her return to the country, another cold was followed by an attack of aphonia, which also yielded to a few inhalations of chlorine vapour. Dr. P. has since treated a case in a medical practitioner, who had tried, among other remedies, repeated applications of strong solution of lunar caustic, without any good effects. The voice was restored to its natural strength in a week or ten days. He suggests that care should be taken that the chlorine be not developed too rapidly. He believes that it acts merely as a local stimulant, and that iodine, or any other exciting vapour, would produce similar results.

TREATMENT OF SCARLATINAL OTORRHŒA.

In the treatment of the otorrhœa, which sometimes follows scarlatina, M. Trousseau employs, instead of simple alkaline or emollient applications, the same topical remedies as would be used in the most severe affections of the mucous membrane or skin—mercurials or the nitrate of silver. He recommends a liniment, consisting of binoxide of mercury, twenty-five parts, oil of sweet almonds and lard, of each five parts. The external meatus is washed out and well dried, and a brush dipped in the liniment is introduced twice a day. By this means, M. Trousseau lately cured a case of scarlatinal otorrhœa, in a little girl, which would otherwise probably have destroyed the small bones of the ear, and produced caries of the petrous portion of the temporal bone. M. Trousseau also recommends the application of a solution of nitrate of silver, in addition to the mercurial liniment; it gives no pain, and may be safely intrusted to the parents of the child. A little binoxide of mercury may also be mixed with oil, and dropped into the ear, which is then to be plugged with cotton wool. As long as there is no perforation of the membrana tympani, these remedies are excellent; they are applicable not only to children, but to adults labouring under otorrhœa, or under that form of eczema which renders the meatus dry, and produces some deafness. This is easily remedied by the preparations described above, if care be taken to keep the tissues moist in the intervals with olive oil. [*Journal de Méd. et de Chir. Pratiques*, Oct. 1850.]

TUMOUR OF THE OPTIC THALAMUS INCLOSING A CALCAREOUS CONCRETION: ABSENCE OF MARKED CEREBRAL SYMPTOMS.

A servant, a young woman, unmarried, died quite suddenly, after a short struggle, having only complained of some confused pain in her head the day before. She had not exhibited any well marked symptoms of cerebral disease. The place of the right optic thalamus was occupied by a tumour, the size of a walnut, encased in a thin lamina of healthy nervous substance, apparently the remains of the thalamus. It projected considerably into the ventricle, and inclosed a calcareous concretion the size of a filbert, of irregular figure. The tissue of the tumour was distinguished from nervous substance, by its greater consistence, and its yellowish pellucid colour; the fresh section had a striated and gelatinous appearance; small earthy particles were disseminated throughout its substance. The tumour, and its enveloping brain substance, became quite detached by maceration in spirit. The ventricles were dilated by limpid serum, and three ounces of limpid serum lay in the subarachnoid space. The veins and sinuses contained less blood than natural. The other organs were healthy; the uterus was gravid.

The tumour seemed, under the microscope, to consist of small cells and granular matter, with a sparing intermixture of fibrous element. [Mr. Bindley in *Ninth Report of Birmingham Pathological Society*, p. 6.]

DR. ZOEHRER'S EXPERIMENTS ON RETRO-VACCINATION IN VIENNA.

The following account of some experiments on retro-vaccination, performed by Dr. Zoehrer of Vienna, is extracted from the reports of the General Hospital at Vienna for 1848 and 1849, published in the *Zeitschrift der K. K. Gesellschaft der Aerzte zu Wien*, for November 1849, and Sept. and Oct. 1850.

Since the year 1842, Dr. Zöhrer has been performing experiments on the transmission of vaccinia from the child to the cow. The results have not been altogether satisfactory, from the cows being neglected by the persons who had the care of them; but, with the friendly assistance of Herr Kotmeier, the bailiff at Gersthof near Vienna, he met with better success in 1848 and 1849.

Experiments. 1. A white milch-cow with brown spots, and fine-skinned, which had calved for the first time three months before, and had the udder and teats well formed, was selected from a herd of thirty. Two deep punctures were made on each nipple on the 9th April, and matter was introduced, which had been transmitted through the human subject since the time of Jenner. Up to the 14th, there was no change, beyond a knotty hardness and increased heat.

The second experiment was made on a dark-brown, thick-hided, pregnant cow, seven years old. The matter, derived from spontaneous cow-pock in 1843, was introduced into the udder.

In the meantime, from the 14th to 16th April, vaccine points were developed in the first cow. Seven of the efflorescences remained hard, with a broad base, and firm exudation in the cellular tissue. When punctured, they gave exit to a scanty tenacious fluid, coloured with blood. The eighth spot, near the end of the right hinder nipple, exhibited on the eighth day a dark, small, translucent ring, with a well-raised margin and deep central depression, and furnished on puncture some perfectly clear lymph. With this a male child, Rudolf, four months old, was vaccinated, by means of four deep punctures. Up to the 20th of the month the punctures presented small indurations, which on the third day exhibited vesicles filled with clear contents, had a small hard dark-red apex, with considerable exudation in the surrounding cellular tissue. On the 26th, desquamation commenced; it was accompanied by obvious febrile symptoms, and was finished at the beginning of May.

In the meantime, crusts had formed on all the pustules in the cow; they left well marked cicatrices. In the second cow, the pocks were not well developed, and what little matter there was, was lost, through the carelessness of those who had the care of the animal.

On the 27th April, a female child, Rosa, 19 months old, sister of the above mentioned boy, was vaccinated with matter taken from his arm. The results were as follows. *First day.* Redness of the punctured spot. *Second day.* No further change. *Third day.* Palpable hardness. *Fifth day.* Formation of small vesicles. *Sixth day.* Enlargement of these, with raising of their edges. *Seventh day.* General febrile disturbance. *Tenth day.* Diarrhœa; excrements fœtid, yellow, thick, at a later period fluid. *Twelfth day.* Tongue loaded; child restless, hot, and sleepless. *Thirteenth day.* Commencement of desquamation. The child was more quiet, and took food, which it had previously refused. *Seventeenth day.* The pocks were covered with small, dark, very firm and thick crusts, which gradually fell off, and left deep cicatrices, of a strong red colour.

At the same time with this case, a female child, T. F., 11 months old, was vaccinated. The results were similar to those which have been just related; and were moreover accompanied by extensive vaccine roseola. From the child T. F. were vaccinated two foundlings, of six weeks old, and one of a fortnight old. In two of the cases six, in one five vaccine efflorescences

appeared; they had a slow course, contained bluish transparent matter, and were accompanied by febrile disturbance; the crusts were hard and darkish, and left deep cicatrices.

On June 16, 1849, Dr. Zöhrer inoculated a cow with vaccine matter transmitted from a retro-vaccination performed in 1842. The animal was three years old, thick skinned, and small, with loose pendulous udders and teats: it had calved three months before. The lymph was inserted into a deep puncture in each nipple. On June 19th, the spots appeared faded, so that there seemed to be little hope of success. On June 21st all the punctures, on both sides, were surrounded with an areola eight lines broad. On June 22nd, there was a pustule developed on the hinder left nipple. The border was very hard, the areola narrow and dark red, and very tender to the touch. The temperature of the udder was raised, and the place where the pustule was felt knotty. On puncturing the pustule, a small quantity of clear lymph exuded, with which, within an hour, Dr. Zöhrer vaccinated a child, F. A., in the Foundling Hospital.

This was on the 22nd of June. On June 25th, the punctures were reddened. On June 26, the punctures had faded, except two. June 27, the indurations had increased. June 28, vesicles appeared, filled with lymph. June 29, the vesicles had extended, and were surrounded with a red areola. Two children were now vaccinated with lymph taken from this case. July 3, the pustules had extended, and still contained fluid lymph. The process ended in the formation of a thick dark crust.

In the cow, no result was obtained from the anterior nipples. The pustule on the hinder right nipple was extensive, hard, and deeply seated in the corium. On June 23 Dr. Zöhrer punctured it, and with the lymph (which was rather opaque and scanty) he vaccinated a child four weeks old, without effect. Both the pocks in the cow passed through their course pretty rapidly, so that desiccation commenced on the eighth day, and on the twelfth day hard dark crusts were present.

Second Descent. From the child F. A., three others were vaccinated. 1. M. J., six weeks old. Six punctures were made; of these five presented hard, small, strongly glistening pustules. The course was slow. The vesicles remained hard, and contained clear lymph even after the twelfth day. 2. Sch. A., ten days old. The pustules were small and hard, and the course the same. The crusts were slow in forming; they were thick, and left deep round cicatrices. 3. M. M., eleven days old. The pustules were small and hard, of the size of linseeds. The course was slow: the pocks remained small until they dried. There were no febrile symptoms in either case; all three had some miliary eruption, but nothing very remarkable.

Third Descent. 1. E. G., was vaccinated. Six pustules appeared, which presented nothing remarkable in their course. 2. W. J., aged nineteen months; and his sister E., aged nine months. Dr. Zöhrer did not see the child till the twenty-third day, when there were tolerably compact dark brown crusts; the pustules appearing to have been in the mean time well developed. 3. St. E., fourteen months old; no result. 4. W. A., ten days old. Six pustules were formed, which passed through a normal course. With these, other children, B. A. and W. A., each twelve days old, were vaccinated; and the lymph was continued to be propagated through the human subject, with encouraging success.

SCHMIDT'S REMEDY FOR TAPE-WORM

The details are extracted from Most's *Encyklopädie der gesammten Medicinischen und Chirurgischen Praxis* (B.I., p. 992, 2nd edition). The composition of the remedy is also presented, though with less fulness, in the *Pharmacopée Universelle* of Jourdan (T. I., p. 313, 2nd edition).

By the process of Schmidt, the tape-worm is said to be expelled in from three to five days, without injury to the patient. A trial of it was made,

under the authority of government, in the Berlin hospital, when the results were found to be so favourable, that the king of Prussia purchased the secret by bestowing a pension of several hundred dollars upon the originator. The plan substantiates the purely empirical fact, that vermifuge medicines, when exhibited separately, are less efficacious than when combined in complex formulæ.

The patient commences by taking, in the morning, the following mixture : ℞ Pulv. rad. valer. min. ʒvi ; fol. senn. ʒij ; aq. ferv. ʒvi ; infunde et cola. Adde sal. Glauber. crystal. ʒiij ; syr. mannæ ℥ij ; elaeosacch. tanaceti ʒij ; M.S. Two tablespoonfuls every two hours, drinking freely at intervals of sweetened coffee. With this he perseveres till seven in the evening. At noon he takes a thin gruel ; and in the afternoon one or two herrings, with the milt. At eight in the evening, the patient has a herring salad, with minced raw ham and oil, sweetened with sugar, plentifully added. Frequently portions of the tape-worm begin now to be discharged. At six in the ensuing morning, he commences the following pills every hour : ℞ Assafœtidæ, extr. graminis, āā ʒiij ; gambog., pulv. rhei, jalap., āā ʒij ; pulv. ipecac., digit. purp. sulph. antim. aurat., āā ℈ss ; sub. muriat. hydr. ℈ij ; ol. tanacet., æther. anisi, āā gt. xv. M. Divide into pills of two grains each, which are to be placed in a well-stoppered bottle ; of these, six pills are to be administered every hour, with a teaspoonful of common syrup. Half an hour after the first dose, a tablespoonful of castor oil is also given. Sweetened coffee is again to be taken freely at intervals during the day. At two in the afternoon, the worm is usually wholly expelled, when the pills are to be discontinued. Should only separate portions be voided, the remedies are persisted with, and a second dose of castor oil becomes requisite. Meat soup is allowed at dinner, and in the evening. On the succeeding day, six pills are exhibited at three different times—morning, noon, and evening. Such is the entire and complicated process. Most adds, that this method of cure has been a hundred times successfully tested : and that it warns young physicians, not to condemn too hastily the complex prescriptions of older practitioners, as there is often produced a *tertium quid* of real efficacy, which could not have been developed in more simple compositions. We leave it to British practitioners to judge, whether this commendation ought to be sufficient to induce them to give a trial to the singular process—ham and herrings included. [Abridged from the *Monthly Journal of Med. Science*, March 1851.]

IMPERFORATE ANUS : LIFE PROLONGED TO THE HUNDRED AND SECOND DAY WITHOUT EVACUATION.

In this case reported by Mr. A. Prichard in the *Provincial Medical and Surgical Journal* for March 5, 1851, a well-formed anus was disclosed on examination, and an operation proposed to remedy the obstruction in the natural passage, but not assented to by the mother. The case is peculiar, as showing the length of time which the infant lived without ever having an evacuation of the bowels, and having been scarcely at all sick. It never threw up anything like fæcal matter, but, as in other children, a little of the mother's milk now and then regurgitated. On examination after death, the organs generally were found healthy, but about the end of the jejunum the bowel began to be dilated, and all the lower part of the ilium was enormously distended—the contents being almost entirely gaseous. The large intestine was also much dilated. At the sigmoid flexure there was a slight contraction, so that the rectum itself appeared like a large and separate pouch, and this was full of yellow and fluid fæcal matter. The termination below was a rounded fibrous cord, as thick as a crow-quill, leading to the anus, and there was not more than a quarter of an inch between the lower part of the pouch, which has been described, and the highest point (about a quarter of an inch), to which a probe could be passed through the natural aperture below.

SPONTANEOUS FORMATION OF POISON IN THE HUMAN BODY.

In an article on the nature and treatment of diseases, published in the *Dublin Quarterly Journal* for February 1851, Dr. Graves relates some cases in proof of an opinion formerly advanced by him, that wounds and accidents, affecting external parts, may give rise to symptoms plainly denoting the operation on the constitution of a poison manufactured, as it were, in the injured skin and subcutaneous tissue.

Case I. A healthy female child scratched her nose with a blunt nail. The wound inflamed, and subsequently festered; and in several days the face, forehead, and at a later period the trunk, became more or less covered with an eruption somewhat resembling ecthyma. The child got well in a fortnight, under the local application of soothing remedies, and the internal use of lime-water with milk, which was given to obviate a looseness of the bowels which followed the appearance of the eruption. It is curious that the matter from the pustules infected three of her little nursery play-fellows. As soon as this fact was noticed, the children were separated from each other, and the nascent pustules were checked in their progress by applying a weak solution of nitrate of silver. They all recovered. The case is interesting, as proving not only that an injury may cause the human body to manufacture a poison capable of infecting the constitution of the individual, but that the matter so formed may be capable of infecting, by contact, other persons.

Case II. Miss G., aged 16, had fever; bed-sores formed on the sacrum and hips, and gave much trouble. Notwithstanding, there seemed to be some chances of her recovery, when, on the twenty-fifth day of her fever, during the nocturnal delirium, she bit off a large piece of her right thumb nail, and injured it to the quick. It inflamed rapidly, and the thumb swelled, the lymphatics of the right arm became indurated, and the whole extremity swollen. After a few days the body was covered with large vesicles, many of which were confluent, and contained an opaque whitish serum: there was also an increase of constitutional irritation and fever. She died on the thirty-second day. In this case it is doubtful whether the poison originated in the bed-sores, or in the injured thumb.

Case III. In the spring of 1848, Dr. Graves saw a young lady labouring under typhus fever, and who, after a long struggle, was apparently about to undergo a favourable crisis, when suddenly the skin of her scalp, which had been blistered previously, and had healed but imperfectly, became erysipelatous. The disease spread slowly at first to the forehead and eyelids, in which matter formed abundantly, and was after some days let out with a lancet. The erysipelas now extended to the neck and between the shoulders, assuming daily a more unfavourable character, and producing, as it spread, much subcutaneous œdema attended with the formation of sero-purulent matter, as is usual in cases of diffuse inflammation. Her state became rapidly worse; vesicles containing sero-purulent matter formed in her skin, and at last many of her joints, both large and small, became the seat of puriform deposit shortly before death.

Dr. Graves thinks that he has been able to trace many of the symptoms, observed in *rupia cachectica*, and in the worst forms of secondary lues and pseudo-syphilis, to the operation of a poison formed in irritated ulcers, whether in the throat or other parts. Hitherto pathologists have considered these constitutional effects to be the result of a poison introduced into the system from without.

SURGERY.

ABSCESS IN THE NECK FOLLOWING SCARLATINA: RUPTURE OF THE INTERNAL JUGULAR VEIN: RECOVERY.

Dr. R. J. Hale related in this Journal for August 1850, a fatal case of ulceration and rupture of the internal jugular vein, following scarlatina. The following case, of which we abridge the account given in the *Union Médical* for August 24, 1850, is reported by Drs. Dépéret-Muret and C. Boulland of Limoges.

Case. Dr. Dépéret was called, on the 13th February 1850, to see a boy, aged 14, who had had scarlatina for eight days. The only treatment employed had been five leeches to the angle of the lower jaw, on account of intense angina with swelling of the parotid region. The patient, when seen, was suffering from violent inflammation of the pharynx with great tumefaction of the tonsils; and the air passages were filled with mucus, the result of universal bronchitis. A dose of tartar emetic produced abundant vomiting; and this was followed by the ejection of a quantity of pus. On the next day, the voice and breathing were free; there was a little fever; desquamation was proceeding freely.

There was a tumour in the left parotid region, extending from above downwards, from the lobe of the ear to the middle of the neck; in front it reached the anterior third of the lower jaw, and posteriorly it became buried under the sterno-mastoid muscle. It was hard, resistant, tender when touched, and immoveable; it seemed to be deeply buried in the tissues. Fifteen leeches were applied round it, to be repeated the next day; and poultices of flour and linseed-meal were ordered to be constantly worn.

February 18. The general health of the patient was satisfactory. The tumour projected more, and was soft and fluctuating. No abnormal sound was heard on auscultation. A bistoury was introduced at its summit, to the depth of about a quarter of an inch, and gave exit to some thick, creamy, inodorous pus, without any blood. It was recommended to allow the pus to escape gradually; and poultices and emollient lotions were prescribed.

February 21. Up to this date nothing had escaped but healthy pus. On this day, the person who dressed the part, observing a fleshy flocculent plug in the mouth of the wound, attempted to remove it by traction. A large quantity of dark blood immediately escaped; this was immediately arrested by pressure on the orifice of the abscess.

February 22. The whole sac was easily recognised to be full of soft semi-coagulated blood. Venous hæmorrhage had evidently taken place; but it did not proceed from the external jugular vein, which was well defined to the outside of the opening of the abscess. A compress was applied, and kept wet with cold vinegar and water; and the patient was desired to keep quiet, and to resist as much as possible all efforts to cough.

February 23. The swelling was much increased in size; the skin was much inflamed and thinned. No murmur nor expansive movement could be perceived in the tumour: the beating of the carotid artery could be heard distinctly, and the pulse could be felt in the facial and temporal arteries. It was determined to extend the original opening, which Dr. Boulland did to the extent of about three centimètres (1·17 inch). A quantity of half coagulated dark blood immediately escaped. Without loss of time Dr. Boulland plugged the aperture with his finger. He then cut, with scissors, the external wall of the tumour, from below upwards. The blood immediately escaped in great quantity; the patient was nearly in a state of syncope, and cried out that he was dying. Balls of wadding were placed in succession on the part whence the hæmorrhage proceeded, so as to plug the abscess. This arrested the hæmorrhage; and the pressure was maintained by a bandage.

February 26. The most superficial balls were removed: they were impregnated with healthy pus, and with a small quantity of blood, evidently that which had remained in the cavity of the abscess. The dressing was completed by some turns of a bandage round the neck and under the axilla of the opposite side.

March 3. The whole apparatus was removed with much care. When the deepest plugs were removed, dark blood was observed to exude; and the pulsations of the carotid artery were easily observed at the bottom of the abscess. Compression was carefully applied as before.

March 9. The patient was weak, but going on favourably. The dressings were soaked with healthy pus, and were almost entirely reserved. Some rigors, followed by heat and sweating, had appeared at regular intervals, but were successfully combated by sulphate of quinine. There was no vomiting nor diarrhœa, and the catarrhal bronchitis diminished daily.

March 16. The dressings were renewed: no blood escaped.

March 23. The purulent pouch had almost entirely disappeared, leaving only a superficial wound at the seat of the incision.

June 26. The only trace of the injury was a cicatrix at the anterior border of the sterno-mastoid muscle. The movements of the neck were perfectly free. During the whole course of the disease, the cerebral functions had never been for an instant disturbed.

In their remarks, the reporters observe that all the cases of this description, which have been hitherto related, have proved fatal. They refer to the instances related by Dr. Alexander King of Glasgow, Dr. J. C. Abill, and Dr. R. W. Smith of Dublin. To these we may add the case of Dr. Hale, to which we have already referred.

This case was remarkable for presenting no adynamic symptoms, such as are commonly observed to attend abscesses of the neck, complicated with extensive disorganisation of tissues. There was only an acute abscess, containing healthy pus, and giving rise to no complication.

After the hæmorrhage was arrested there was danger:—1. That the brain would be affected by the inability of the blood to return through the compressed vein; and 2. That consecutive phlebitis might occur, which would be even more dangerous than the rupture of the vein. To these sources of danger, mentioned by the authors, we would be disposed to add a third; viz., the entrance of air through the opening in the vein. We are not aware that this has occurred in any of the cases, analogous to the present one, which have been recorded; but we think it quite capable of occurring.

The authors, in conclusion, remark that such cases as these point out that particular attention should be paid to inflammation and abscess of the neck, arising in the course of scarlet fever.

CANCRUM ORIS SUCCESSFULLY TREATED BY THE LOCAL APPLICATION OF CAMPHOR.

Dr. Deutsch of Nicolai, in Upper Silesia, in an essay on noma, published in the *Journal für Kinderkrankheiten* for January and February 1851, speaks highly of the efficacy of camphor as a local application in this disease. It must be observed, that cancrum oris, in Germany, generally attacks the exterior of the cheek, while in England and France the interior of the mouth is the part mostly affected. After briefly referring to the numerous remedies which have been proposed, but which very often fail in producing recovery, Dr. Deutsch observes:

"Under these circumstances I do not hesitate to mention a remedy, the remarkable operation of which has been observed for several years both by myself and by others; I allude to camphor. The mode of application is as follows. The camphor is rubbed and moistened with a few drops of spirits of wine, so as to form a thickish mass, almost of the consistence of ointment.

This is laid, as thick as the back of a large knife, over the whole surface of the noma, and extending at least one-third of an inch beyond. If there be much secretion, the layer must be removed at the end of an hour, and a fresh one applied; if there be less secretion, it may remain on for two or three hours. The first effect produced by this remedy, is an arrest of the degeneration, which remains at a stand for twenty-four hours or more; during this time also the secretion usually loses in part its offensive odour and its acridity. A positive result now appears; the edges of the sore now exhibit a very evident lively-red line of demarcation, secreting pus; and granulations appear. The camphor now need be no more applied to the edge, but only to the more degenerated interior part; the edge must be dressed with an ointment of oil of turpentine and opium. When the granulations have nearly filled the sore, the camphor entirely falls off, and common dressing may be applied."

Dr. Deutsch illustrates his observations by the relation of several cases, in which the treatment proposed by him had been found effectual after other means had failed.

BORAX AS AN APPLICATION TO GANGRENOUS BUBOES.

At the meeting of the physiological and pathological section of the Medical Society of Vienna on June 18, 1850, Dr. Effenberger stated that he had applied a solution of borax, in the proportion of from one to two drachms in a pint of water, to a large number of patients who suffered from gangrenous bubo, with great success. He had had fifty cases in one year; not one had died, although there were several very severe cases, and in one the femoral vessels were laid bare. The solution was applied by means of charpie, so as to cover the edges of the sore. It was very essential that the charpie should be very frequently renewed by night and day; and to the neglect of this precaution, he attributed the failure of this practice in the hands of other surgeons. (*Zeitschrift der K. K. Gesellschaft der Aerzte zu Wien*, Nov. and Dec. 1850.)

SUBCLAVIAN ANEURISM SUCCESSFULLY TREATED BY LIGATURE OF LEFT SUBCLAVIAN ARTERY: APPEARANCES ON DISSECTION A YEAR AFTERWARDS.

This case, which occurred under the care of Dr. J. M. Warren of Boston, U. S., was reported in the *American Journal of Medical Sciences* for January 1849, and an abstract was given in the Digest of this Journal for April 1849, p. 381. To this abstract we must refer our readers for the peculiarities of the case; merely observing that the subclavian artery was found to run obliquely across the neck, parallel with the edge of the trapezius muscle, and in company with the cervical plexus.

In the *American Journal of Medical Sciences* for Jan. 1851, Dr. Warren states that, on Sept. 14, 1848, nine months after the application of the ligature, the patient was quite well, and had perfectly recovered the use of the arm. The aneurismal tumour had in a great measure disappeared, though more prominent than immediately after the ligature of the vessel. On its surface was a large arterial branch, so incorporated with it as at first to give the idea of a return of pulsation in the whole mass, but which by more careful examination could be separated from it. The pulse at the wrist still remained less strong than in the corresponding artery of the other side. The patient was subsequently seized with typhoid fever, from the effects of which she died, after an illness of three months.

On post-mortem examination, no tumour nor other marks were observed at the point formerly occupied by the aneurismal sac. The vessels and nerves were easily exposed, from the great loss of adipose substance. The subclavian artery, from its origin to the internal edge of the scalenus anticu

maintained its original size ; but here it suddenly terminated. From this spot to the aneurismal sac was extended a flat cord, an inch and a half in length, seeming to be composed of little more than condensed cellular membrane. The aneurismal sac had contracted to a bulbous form, and was about twice the size of the vessel in its normal state ; the enlargement suddenly ceasing at the point where the vessel is embraced by the two heads of the median nerve, and the vessel regaining its natural size. On its surface was the supra-scapular artery, in this case a branch of the transverse cervical, greatly enlarged, and which gave use to the apparent pulsations in the tumour before death. The vessels forming the thyroid axis were of twice their natural dimensions. The internal mammary was enlarged, and given off from the thyroid ; it was apparently through this, by means of the inosculations of the intercostals with the thoracic, and of the posterior scapula with the subscapular, that the collateral circulation had been established.

GLANDULAR ENLARGEMENTS IN THE GROIN AND AXILLA OF YOUNG PERSONS ; TREATMENT BY CAUSTIC POTASS.

In a paper on Issues and Caustics, published in the *Dublin Quarterly Journal of Medical Science* for February 1851, Dr. B. G. Darley refers to the form of constitutional or sympathetic enlargement of the glands of the groin, frequently met with in young men, and not the consequence of the venereal virus, but rather the effect of a weakened and cachectic constitution. This tumour is very indolent in its nature ; a long time elapsing before suppuration is established, and resolution is not a common termination. Dr. Darley treats these tumours by making a tolerably sized eschar with caustic potash in the early stage, and covering it with a small poultice. The tumour will be found to have disappeared when the eschar separates.

Allied to this is a tumour often met with in the axilla of young persons. A young man applies for advice, with the arm either in a sling or supported by the other hand, and the shoulder depressed and pushed forward ; and there is much anxiety and suffering in his countenance. If this be treated in the common way, we have to wait long before it suppurates ; and if it be opened, only a small quantity of thick pus escapes. The opening will soon close, and the abscess point in another direction, leaving sinuses which are tedious in healing. Dr. Darley treats such tumours by making a small eschar with caustic potash in the very beginning, when they are hard and indolent. They must not be mistaken for the acute abscess frequently met with in this situation, and easily treated by incision.

EXTIRPATION OF THE GLOBE OF THE EYE FOR A NON-MALIGNANT DISEASE.

Mr. A. Prichard, of the Bristol Infirmary relates a case of this kind. The sight of the left eye had been lost for many years, and the patient was harassed with constantly occurring attacks of inflammation, sleeplessness, and intense pain. He attributed the disease to a piece of iron having entered the eye, and which had never been extracted, and which he complained of feeling rolling about from side to side. On a subsequent examination of the eye, no foreign body could be discovered, but the lens had disappeared, and the capsule was collapsed, hard, and opaque. A thick and firm layer of fibrin separated the sclerotic and choroid, through their entire extent, and upon the outer side of the globe of the eye there was a deep oval cavity, as large as a dried horse-bean, and of a very similar form, situated in the middle of the fibrinous exudation. This was probably the cavity of an abscess. This is the first recorded case, as far as is known to Mr. P., in which the eye was extirpated for a disease not malignant. The freedom from the intense neuralgic pain, after the operation, was complete [*Prov. Med. and Surg. Journ.*]

THE HOSPITALS OF LONDON. No. IV.

BY DR. CORMACK AND DR. SEMPLE, ASSISTED BY NUMEROUS REPORTERS.

THE VITAL STATISTICS OF HOSPITALS.

At p. 181, a very important letter appeared on this subject, by Dr. G. Owen Rees of Guy's Hospital. The topic is adverted to in many communications, which have been sent to us by gentlemen who are interested in establishing an uniform and satisfactory system of registering the recoveries and deaths in the different metropolitan hospitals. Though it would still be premature to decide upon the merits of the various suggestions which have been so kindly forwarded for our assistance, we think that it may be useful to give, in this place, the following extract from a letter received from Mr. J. C. Wordworth, Assistant-Surgeon to the London Hospital. "In addition to the points embraced in the table of Dr. G. O. Rees, cognizance ought to be taken of the time which has elapsed between the admission into hospital, and the death of the patient. In small hospitals, and also in the London Hospital, the deaths soon after admission greatly exceed those occurring within the same period in the larger institutions, and in those which receive few casualties. In the London Hospital, from the great number of severe accidents admitted, the number of early deaths is of course very numerous."

ST. THOMAS'S HOSPITAL.

The following is a list of the medical and surgical staff, with the date of each officer's election.

Consulting Physician. Dr. H. S. Roots.

Physicians. Dr. T. A. Barker; Dr. H. B. Leeson; Dr. Risdon Bennett.

Surgeons. J. H. Green, Esq.; J. F. South, Esq.; G. Macmurdo, Esq.

Assistant Physicians. Dr. R. H. Goolden; Dr. D. W. Cohen; Dr. T. B. Peacock.

Assistant Surgeons. S. Solly, Esq., F. Le Gros Clark, Esq.; J. Dixon, Esq.

Obstetric Physician. Dr. C. Waller.

Lecturer on Pathology, with Clinical Duties. John Simon, Esq.

Resident Medical Officer. R. G. Whitfield, Esq.

The site of this magnificent establishment was formerly occupied by a convent, founded by Mary Overie, who was the daughter of a ferryman, and took her name from the nature of her occupation, *over rie, over the river.* She endowed this convent with the money she inherited from her father, together with that which she acquired by following the same calling herself. The convent was converted into a college of priests by a noble lady of the name of Swithin, and, after existing above a century, was burnt down in 1212; and the temporary building, which was erected during its reconstruction, was afterwards used as an almonry for "indigent children and necessitous proselytes", and dedicated to St. Thomas à Becket. In the fifteenth century, St. Thomas's Hospital was munificently supported by the lord mayor and sheriffs of London; but in 1538, it was claimed as church property and surrendered to Henry VIII. Its yearly income, at that time, was estimated at £266:17:6. Henry VIII intended to endow St. Thomas's Hospital for the reception of lame, wounded, and diseased soldiers, and it was to have been designated the Hospital of the Holy Trinity; but his death interfering with this plan, the citizens of London renewed the benevolent design, and, with the sanction of Edward VI, formed a board of inquiry as to the best mode of relieving the miseries of their more unfortunate brethren.

The result, as regards the foundation of St. Thomas's Hospital, was that they purchased of Edward VI the manor of Southwark, which included the site of the hospital, for £647 : 2 : 1. The hospital had been for a short time unoccupied, and was falling into decay, but the citizens repaired and enlarged it in the year 1551, at the expense of £1000, and made it capable of receiving three hundred patients.

In 1552, the following officers were appointed to the hospital, viz. :—A hospitaller, or chaplain, at the annual fee of 10*l*. Clerk, 10*l*. Steward, 6*l*. 13*s*. Butler, 5*l*. Cook, 8*l*. Physicians and chirurgeons, each 15*l*.

About a month before his death, King Edward VI, by royal charter bearing date June 6th, 1553, incorporated the lord mayor and commonalty of the city of London, in succession, as perpetual governors of St. Bartholomew's, Christ's, Bridewell, and the King's Hospital, as this hospital had been designated during this reign ; but it was now styled, "The Hospital of St. Thomas the Apostle".

In 1693 it was found that the hospital was suffering from the ravages of time, and that it would be necessary to rebuild it. Private charity was soon roused to effect this object, and among others, Sir Robert Clayton, lord mayor and president, contributed 600*l*., and subsequently endowed it by will with 2,300*l*. more ; and Thomas Guy, besides other large donations, rebuilt and fitted up three new wards. By such means the Hospital of St. Thomas became adapted for the reception of the sick, and by the gradual improvements in medical science, became one of the most important schools of medicine in Europe.

It is gratifying to find, that so early as the year 1585 the governors of this hospital set their faces against all jobbing or favouritism in the appointment of their medical officers, as we find by the following minute, dated June 21, 1585. "At this court, Thomas Crowe, son of Wm. Crowe, surgeon, was a suitor for the reversion of a surgeon's room in this house. He was answered that he could have no reversion granted him, for that it is contrary to the orders of this house, but if he be a suitor when any shall fall, and he shall be known to be a fit and able man to take upon him such a charge, that then he shall be favourably considered."

It appears that the surgeons of St. Thomas's were early among the most distinguished members of the profession, holding the office of serjeant-surgeon to the reigning monarchs. In 1641, Edward Moline, one of the surgeons to this hospital, was sent for to York by Charles I, to attend him in sickness ; but, in 1643, he paid dearly for this distinction ; for the president, treasurer, and governors, received an order from the honourable House of Commons then assembled, to displace Edward Moline, one of the chirurgeons of St. Thomas's, from his said place ; for that he was lately taken at Arundel Castle in arms against the Parliament, and for the placing of one Mr. King Clure, chirurgeon, in his place. This said order was read and considered, and in obedience thereunto, "this court doth now order", say the minutes, "that the said Edward Moline shall be and is hereby discharged and displaced from his place as surgeon, but as touching the placing of the said King Clure in the place of the said Edward Moline, it was now also agreed that (before election of a surgeon into the said place) a petition should be drawn and presented to the same honourable House of Commons by the president and governors of this house, to grant their favour, and permit them to confirm Mr. Thomas Hollyer, chirurgeon, who, for fourteen years together, hath him exercised in this hospital, and was formerly a servant to an ancient surgeon of this house, and by the appointment of the said governors, in the absence of this Edward Moline, hath supplied his place for eighteen months this last past". The result of this petition was, that the governors were left to their free election, and Thomas Hollyer was elected accordingly, at a salary of 65*l*. per annum : this sum being granted to him on the following considerations :—for ordinary cures, 40*l*. ; for cutting for

the stone, 15*l.*; and for curing scalled heads, 10*l.* In 1660 King Charles II sent a letter to the president, treasurer, and governors, on behalf of his friend Edward Moline; whereupon the court, after a long debate, "willing to yield all due obedience to his majesty's royal pleasure, and yet withall not to bring a new charge upon this house by employing four surgeons, doth declare that the said Edward Moline be readmitted to his place of a surgeon of this house, as to the cutting for the stone and other ordinary cures, and that the pay of the other surgeons be divided with him until a vacancy should occur, then the number to be again reduced to three". As Mr. Moline, however, was not satisfied with this arrangement, the court eventually resolved that he should be freely and unconditionally restored to his office; and Mr. Hollyer was made a fourth surgeon, with full pay.

The ignorance of the medical profession in the sixteenth century is generally acknowledged, and a very striking proof was exhibited by the difference of opinion which prevailed among the fourteen royal physicians as to the nature of the fatal malady by which Charles II was carried off. The majority of them considered the attack to be apoplectic, but some thought it to be a fit of epilepsy, while others determined to call his complaint a fever, and to administer bark. But, ignorant as the physicians undoubtedly were at this period, it would appear that the surgeons were deemed to be still more so, and they were even forbidden to prescribe, as we find by the following minute in the year 1689. "Ordered that the ancient rule of this hospital, that no chirurgeon shall give any physic to any patient admitted into this house, but that the doctor alone be left to prescribe physic to all patients, be confirmed, and for the future strictly observed". It is, however, curious that, notwithstanding this restriction to the usefulness of the surgeons, we find their important services admitted in the following resolution, passed in 1691. "We are also of opinion that *one* doctor, and *three* surgeons, are sufficient for the service of the hospital".

In the year 1702, the pupils of the hospital are alluded to, under the name of *cubbs*, and we find an order limiting the number of four *cubbs* to each surgeon. This rule continued in force until 1760, and then it was abrogated only in consequence of the example set by other hospitals, as we find by the following resolution: "That as other hospitals are unlimited in the number of their pupils, it be so at the hospitals of St. Thomas's and Mr. Guy's."

To one of the surgeons of St. Thomas's Hospital is due the honour of having first established an HOSPITAL ANATOMICAL SCHOOL. The barber-surgeons of that day were in the habit of giving lectures on "anathomy" in their own hall, but they forbade the pursuit of private "anathomy"; but William Cheselden braved their edicts, and gave lectures on anatomy within the walls of this hospital. In process of time, it would appear that not only were pupils admitted to see the practice of the hospital, but some measures were adopted for securing their attendance, and we accordingly find the following minute made Jan. 27, 1737: "The three surgeons of this hospital having attended according to the directions of a former committee, and upon hearing the account of the manner of examining and certifying for their pupils in this hospital, and looking into the printed form of certificates;—it is ordered that the word 'diligently' in the printed form be left blank in order to be inserted or left out as the occasion shall require."

In 1760, it appears from another minute that pupils were admitted, under proper regulations, to witness the practice of both the Borough hospitals, after they had duly entered at either. It is a pity that these magnificent institutions are not combined, at least so far as medical teaching is concerned. Were they united in this way, and were the teachers well paid from the ample resources at command, and selected solely on the ground of pre-eminent merit, a greater medical college would be the result, than any now existing in London or elsewhere. The continuation of our history we must reserve for another occasion.

ROYAL LONDON OPHTHALMIC HOSPITAL, MOORFIELDS.

Consulting Physician. Dr. Farre.
Consulting Surgeon. John Dalrymple, Esq., F.R.S.
Physician. Dr. F. J. Farre.
Surgeons. Gilbert Mackmurdo, Esq., F.R.S.; James Dixon, Esq.; George Critchett, Esq.
Assistant-Surgeons. William Bowman, Esq., F.R.S.; Alfred Poland, Esq.

NOTICE OF THE TREATMENT OF CERTAIN CASES OF ENTROPION BY MEANS OF COLLODION. REPORTED BY J. CUMMIN TOSHACH, ESQ.

Collodion has been used at this hospital almost ever since its introduction as a surgical dressing; and though we believe it has been employed in the treatment of certain examples of entropion in other quarters, and perhaps independently, we hope the following notice of so useful an agent will not be deemed out of place, especially as it has been shewn in a variety of instances to be a perfect substitute for the somewhat severe operations, to which patients have hitherto been content to submit for the relief of this most troublesome affection. If we mistake not, it was Mr. Ledger, the intelligent house-surgeon of this hospital, who first suggested its employment to Mr. Bowman, in whose practice we have chiefly witnessed its powers.

The most frequent cases of entropion are those affecting the lower lid in elderly persons suffering from ophthalmia. The spasm of the orbicularis, the forcible squeezing together of the lids, occasions an inversion of the lower one, owing to the relaxation of the integument. The inversion having once taken place, tends immediately and directly to aggravate the ophthalmia and the irritability of the organ, and this to perpetuate and increase the entropion. If the inversion is slight, the margin of the lid is turned against the globe, and the lashes lie flat upon the sclerotica and cornea, rubbing the conjunctiva, but often with less irritation than might be expected, and always with less than is occasioned by that inversion or displacement of the cilia in which their free ends are pointedly turned against the eyeball. If the inversion be still greater, the ciliary border is turned completely over, so that the cilia are bent under and are received as it were against the mucous surface of the lid, in the sulcus which always exists along the lid in consequence of its being rolled inwards upon itself. In this position they give less pain, but in both conditions they constitute a serious source of discomfort, and prevent the cure of the ophthalmia. If allowed to remain for any length of time, they often lead to opacities of the cornea and other secondary disorders.

In this form of entropion an operation has commonly been required, and that now commonly resorted to, consists in removing a horizontally elliptical piece of the integument close to the ciliary border, and closing the gap by fine sutures. Other modes of fulfilling the same indications have been adopted with more or less success, and when patients have been unwilling to submit to any of them, the best substitute, and that a most inefficient one, in many cases, has been the fixing the lid in place by means of a piece of adhesive plaster, which is often difficult of retention, and always unsightly.

The following cases, which are among those that have been treated by Mr. Bowman, will show that the Collodion, properly applied, affords not merely temporary but permanent relief in this variety of entropion.

Case 1. J. P., æt. 61, female, presented herself at the hospital, for what she called a cold in the left eye, which had existed twelve or fourteen days, and for the relief of which she had been under treatment at another hospital, where she had given her some eye-water. After attending several times without benefit she applied here. On examining the eye, Mr. Bowman found that the ophthalmia was dependent on an entropion of the lower lid, it being just sufficiently inverted for the cilia with their convex surfaces to rub against the ocular conjunctiva. Mr. Bowman, on turning his attention to the right eye, observed that there was in this eye also an entropion, but

without much accompanying ophthalmia: the inversion in this eye being complete, the cilia were not rubbing against and irritating the conjunctiva, but were lodged in a longitudinal sulcus extending the whole length of the lid, and corresponding to the attached border of the tarsal cartilage.

For the relief of the ophthalmia in the left eye, collodion was applied to the lower lid, in the manner and with the precautions to be presently mentioned. It was also applied to the right lower lid, to restore it to its natural position. No other remedies were employed. She left with directions not to rub the collodion off; and in two days afterwards the patient came with the ophthalmia in the left eye quite well, and no inversion. On the right side, the tendency to inversion was much diminished, and the collodion was applied again. This application was successful.

Case II. J. L., ætat. 70, an old man, was to have an artificial pupil made in his right eye. On presenting himself for operation, it was found there was an entropion of the lower lid, and considerable concomitant ophthalmia. In this state of things, it was impossible to think of proceeding with the artificial pupil. Collodion was therefore applied to the lower lid, and the patient, living some distance out of town, was told to return in a week, which he did; when the ophthalmia had entirely ceased, and the entropion was no longer present. After being in the hospital two or three days, the artificial pupil was made, without any undue inflammation following the operation. In this case, had the collodion not been used, it would have been requisite to have removed a portion of skin, as in the ordinary operation for entropion, previously to attempting to make a new pupil; but by a very simple means surgical interference was obviated, and a painful proceeding, often submitted to with reluctance, was rendered unnecessary.

In the following case it failed, through the neglect of the patient to have it replaced at the proper time.

Case III. R. M., æt. 70, had had entropion of the right lower lid for six weeks, with ophthalmia, when the collodion was applied on the 24th March, 1850. On the 4th April it still adhered effectively, and the inversion was prevented. He did not come again till the 18th April, when the collodion had been displaced several days, and the eutropion had returned. It was then replaced, and also on the 2nd and on the 9th of May; and for the time gave complete relief. After this he stayed away three weeks, during which the entropion returned under a fresh attack of ophthalmia; and as there was no prospect of his being able to come at more frequent intervals, to have the treatment efficiently carried out, Mr. Bowman recommended him to submit to the removal of a piece of the integument in the ordinary way, to which he readily consented, and by which he was cured.

There are other cases of entropion, the result of aggravated or long continued ophthalmia, with much photophobia and lacrymation. The following examples will show that these also are amenable to the collodion treatment.

Case IV. S. L., æt. 39, female, states that five months prior to applying to this hospital (January 20, 1851), her eyes became suddenly bad; that she had been under treatment all that time without any benefit. The right eye was the worst, in which she states there had been an inversion of the lower lid since the commencement. She has at present great intolerance, and profuse lacrymation. There is an opacity covering the upper part of the cornea of the right eye. When she first presented herself she was ordered a blister behind the right ear, and some lead lotion. On the 27th, collodion was applied to the right lower lid. On the 30th, she came back, with the collodion displaced and the entropion restored; but the collodion was reapplied on that day, and on three occasions afterwards, at intervals of three days; when, on the 10th of February, she is much improved; and on the 24th of March she comes with the entropion cured, the opacity of cornea alone remaining. From the 27th of January she had been taking gr. j of quinine twice a-day.

For the following we are indebted to Mr. Bowman's notes of cases in private practice.

Case v. 19th December. Miss ——, æt. 13, from the age of six has suffered twice annually from an attack of ophthalmia, with intolerance. For the last three years has had constant and extreme intolerance, so as hardly ever to open the eyes. Skin cold; pulse languid. Is thin, and grows fast. Bark does not agree with her. Has taken steel and various remedies, under different practitioners. On examination, the right lower lid is found inverted, the left conjunctiva is red in parts, but neither globe can be rendered visible. Tincture of iodine on outside of lids. Cod-liver oil 3 j to 3 iv twice daily. Exercise three times a day in all weathers, well clad. A brine bath at 70 degrees F. every morning, followed by friction. Plain nutritious diet.

January 15. Is much better in health. Spirits and complexion better, and is more muscular. The right lower lid is still inverted, but the eyes are more often open for an instant, and are less injected. I got a view of the two corneæ: the right nearly clear, slightly rough at the margin; the left a little rough and dull near the pupil. Her mother says they have not been seen for two years before. To continue the same treatment.

January 25. The amendment continuing, and the spasm and photophobia lessened. I put collodion below the tarsal border of the right lower lid, averting the lashes.

February 13. The entropion was cured by a single application of the collodion. When the collodion came off at the end of a week, the inversion once showed a tendency to return; but the lid was immediately 'righted' by the mother, and no further displacement has occurred. Rep. Syr. Fini Iodid. ʒ j twice daily.

March 12. The entropion appears quite cured. Her general amendment goes on under the same remedies.

In the application of collodion for the relief of entropion, certain precautions are to be observed; otherwise it may fail in its intended effect.

1st. The collodion itself should not be too dilute. It should be thick and syrupy; in short, it should be concentrated.

2nd. Care should be taken that the surface on which it is to be applied is properly *dry*, and free from any moisture: therefore it is always necessary to wipe the surface before application; otherwise it will not adhere with any degree of firmness, but will soon fall off. With attention to the above caution, it adheres very firmly. There are, however, many cases in which the outer surface of the inverted lid is excoriated by constant wetting by the tears; in which it is desirable to delay the application till this worst state is relieved. A few days are usually sufficient for this purpose.

3rd. During the application, and while evaporation is going on, the position of the head should be attended to. The vapour may irritate the conjunctiva, and a slight increase in the flow of tears take place. To prevent these flowing on to the collodion at the time of its application, it is necessary that the head be inclined to one side, so that the tears may drop from one corner of the eye, and not run over the lid and cheek.

It does not seem very important how much of the integument is covered by the collodion, so long as the contraction is sufficient to remedy the inversion; and the best way to judge of this, is to bring the lid into place, and raise the skin from the cheek towards the tarsal border, before commencing the application of the collodion. It is necessary to apply it close up to the ciliary border, in order to produce the contraction along that border. If this be done, it is less essential to smear it far down towards the cheek. Where the integument is very lax, a very considerable surface of it may be covered.

With these precautions in view, the application is proceeded with as follows. The lid being restored to its natural position, it is held there while the collodion is being applied, by making gentle traction outwards on the integument below the outer canthus. In this way the skin of the lower lid is horizontally grooved, while at the same time it is left exposed, so as to be free to receive the collodion. It should be held in this way till the collodion has contracted at least to such a degree as may be sufficient to maintain the

right position of the lid during the further stages of the contraction. Very often one application of the collodion is sufficient to cure an entropion; but if a tendency to return manifests itself, it must be repeated at intervals of three or four days or a week.

It must be remembered that the collodion is not proposed as a cure for every case of entropion. In those forms which depend on contracted cicatrices or a distorted cartilage, when the tarsal edges may be irregular or much thickened, the ordinary modes of cure by operation must still be resorted to, but confining the treatment by collodion to those forms which are recent and uncomplicated with serious structural change, it will be found that it is an invaluable means of remedying a great and troublesome deformity.

[The historical notice of this hospital, the oldest and largest of the ophthalmic hospitals of this kingdom, is necessarily deferred to a future occasion.]

MISCELLANEOUS INTELLIGENCE.

Sale of Arsenic Regulation Act. The principal provisions of this Act, which was introduced by the Earl of Carlisle, and has recently passed, are as follows. The seller of any quantity of arsenic must enter in a book, kept for the purpose, the name and residence of the purchaser, and the purpose for which he alleged he wanted the article: the purchaser must also, in all cases, sign his name, and, except in certain cases, the arsenic should not be sold except in presence of a witness. With the view of preventing accidental poisoning, it has been proposed to add some foreign colouring matter to the arsenic, so that it may not be mistaken for flour, meal, carbonate of soda, or the like. But as the introduction of foreign matters might interfere with some of the purposes to which arsenic is applied in arts and manufactures, it is determined that no person shall sell less than ten pounds weight of uncoloured arsenic, unless it were stated by the purchaser that he wanted it for some purpose in which the introduction of an adventitious colour would be injurious. It is proposed that soot be employed as the colouring matter. *Arsenic is to be sold to none but male adults:* and where less than ten pounds of uncoloured arsenic is required, there must not only be the signature of the purchaser, but also the presence of a witness known to the seller.

APPOINTMENTS.

Elin, George, Esq., appointed House-Surgeon to the Birmingham General Hospital.

Hutton, Dr. Charles, elected Physician-Accoucheur to the General Lying-in Hospital, York Road, in the room of Dr. James Reid, resigned.

Lonsdale, E. F., Esq., appointed Surgeon to the Orthopædic Hospital.

OBITUARY.

Allan, James, M.D., Deputy Inspector-General of Hospitals and Fleets, Surgeon to Haslar Hospital, at Portsmouth, aged 58, on 18th March.

Bowie, John James, M.D., at Bentinck Terrace, Regent's Park, aged 31, on 12th March. He was for several years one of the Assistant Physicians to the Hospital for Consumption at Brompton, but resigned his office about a year ago, in consequence of ill health. His disease was phthisis pulmonalis, though at first it assumed a different character.

Inglis, James, M.D., formerly Physician to the Ripon Public Dispensary, at Green Royde, near Halifax, aged 37, on 8th March, of disease of the heart.

TO CORRESPONDENTS.

TYPHUS AND TYPHOID FEVER.

To the Editor of the London Journal of Medicine.

Hull, March 6, 1851.

Sir,—I was under a mistake, it appears, in ascribing to Dr. Wm. Jenner the opinion, that "occasionally, though very rarely, in typhoid fever with the rose rash, the follicular lesion is wanting". Nevertheless, I believe the opinion, apart from *his* authority, to be correct. As Dr. Watson distinctly asserts the same pathological truth, I think it probable I may have had the following passage from his Lectures in my mind, which I inadvertently confounded with the statements of Dr. Jenner. After describing the *spotted* or *rubeoloid* epidemic fever of 1838, Dr. Watson adds,—"I have looked for them (ulcers in the bowels) in many cases that have proved fatal in the Middlesex Hospital, and have discovered *neither ulceration nor any other apparent change in the follicles of the intestines. Still, in my own experience, such ulcers have been vastly more often present than absent.*" (*Watson's Lectures on the Practice of Physic*, 1st ed., vol. ii, page 689.) By inserting this explanation in your next Journal, you will much oblige,

Sir, yours faithfully, Humphry Sandwith.

Physician to the Hull Infirmary.

Pneumonic Paralysis. We have received the following letter from Mr. Thos. Underhill, Jun., and shall be glad to receive information on the same subject from those who have it to give.

To the Editor of the London Journal of Medicine.

Tipton, Staffordshire, 27th February, 1851.

Sir,—I have read with much interest in the London Journal of Medicine for this month, p. 163, your account of Dr. Macario's paper on what he terms "Pneumonic Paralysis"; and as the two cases recorded in that paper are very similar to one which has lately occurred in my practice, I am induced to forward to you the following notes.

Richard ——, aged 44, a labourer, of delicate constitution and nervous temperament, was seized on the 20th December, 1850, with acute pneumonia, commencing in the lower part of the left lung, and rapidly involving the whole of that organ. The symptoms soon assumed a typhoid character, as was anticipated from the constitution of the patient and the extent of the disease. There was some, but not much, delirium. I applied a large blister to the affected side; and in other respects adopted the ordinary treatment. On the 27th, he was decidedly convalescent. On the 28th, I found the improvement going on; he said that he had slept well, perspired freely, and expectorated copiously. There was a very distinct subcrepitant rhonchus. When I proceeded to feel his pulse, *he gave me his right arm, telling me at the same time that he could not move the left;* and that he supposed he had lain upon it. Upon examination, I found that the left arm was completely paralysed. He had no giddiness and no headache. Sensation was not impaired in the hand or arm; there was neither a feeling of numbness, nor of tingling; but when I raised the arm, it fell back upon the side like a dead weight. I directed daily friction of the limb with a stimulating liniment. On the 6th of January, 1851, he was able to walk about within doors; and with the exception of complete persistence of the paralysis as described, he was going on most favourably. On the 12th of January, he announced to me that he was able to move his fingers. On the 16th he could move the wrist-joint, though with difficulty; on the 20th he could bend the elbow. The arm gradually got stronger; and on the 20th of February he resumed his ordinary occupation.

I do not offer any remarks upon the complication of the pneumonia with paralysis. The relation (if any) between the two affections can only be solved by those who have large opportunities in hospitals of observing the former disease.

I am, Sir, your obedient servant, Thomas Underhill, Jun., M.R.C.S.Eng.

ORIGINAL COMMUNICATIONS.

ON IRRITABLE UTERUS.

By F. W. MACKENZIE, M.D., Physician to the Paddington Free Dispensary for the Diseases of Women and Children, Fellow of University College, etc.

A PAINFUL condition of the uterus, when not occasioned by displacement, inflammation, or any appreciable organic disease, constitutes the *hysteralgia* of some authors, and the *irritable uterus* of Dr. Gooch. It is met with in practice in various degrees of intensity, from slight uneasiness to a disease characterized by the most excruciating suffering. In its severest forms it is comparatively seldom met with; but, otherwise, it cannot be regarded as an unusual disease. Although it would essentially appear to consist in a mere lesion of innervation, and to be a very simple and remediable disorder, it is often found to be the reverse; and in some instances has baffled the resources and the ingenuity of the most experienced physicians. I propose, in the present communication, to draw attention to some facts which have come under my observation in relation to this disease, and to submit such inferences as appear to me to be deducible from them.

The slighter forms of this malady are characterized by pain in the uterine region, increased by standing or walking, and somewhat relieved by lying down. The pain extends, or rather radiates from the uterus to the groins, hips, thighs, and loins. A sensation of bearing down of the womb is often felt; there is frequently leucorrhœa and sometimes dysmenorrhœa. On a digital examination, the uterus is found to be extremely sensitive to the touch, but it is neither displaced, nor perceptibly diseased. The constitutional derangement attending this uneasiness is seldom of a febrile character; on the contrary, the general health is for the most part depressed, the circulation is languid, the pulse feeble, and the condition of the nervous system is that of weakness and irritability. The digestive organs, so far as I have observed, are seldom unaffected; they are generally in an irritable and disordered condition, and their secretions are either faulty or deficient. On inquiry into the antecedent circumstances of the patient, it

will often be found that she has suffered from severe mental affliction, trouble, or uneasiness, or has experienced some sudden fright or emotion, or else that she has undergone physical privation or fatigue; and that, as a consequence of these, spinal irritation and anæmia, in various degrees, have resulted. This latter condition is an almost constant concomitant, as well as antecedent of the malady; and, judging from the history of the cases which I have collected, would appear to be its principal predisposing cause.

The more severe form of this disease has been very graphically described by Dr. Gooch. He remarks that a patient, suffering from irritable uterus, complains of pain in the lowest part of the abdomen along the brim of the pelvis, and often also in the loins. The pain is worse when she is up and taking exercise, and less when she is at rest in the horizontal posture. If the uterus is examined, it is found to be exquisitely tender. As soon as the finger reaches, and is pressed against, the uterus, it gives exquisite pain; this tenderness, however, varies, at different times, according to the degree of pain which has been latterly experienced. The neck and body of the uterus feel slightly swollen; but this condition also exists in different degrees; sometimes being sufficiently manifest, sometimes scarcely or not at all perceptible. Excepting, however, this tenderness, and the occasional swelling, or rather tension, the uterus feels perfectly natural in structure. There is no evidence of scirrhus in the neck; the orifice is not misshapen, nor are its edges indurated. The circulation is but little disturbed; the pulse is soft, and not much quicker than is natural, but it is easily quickened by the slightest emotion. In a few instances, however, there has been a greater and more permanent excitement of the general circulation. The degree in which the health has been reduced has been different in different cases. A patient who was originally delicate, who has suffered long, and has used much depletory treatment, has been, as might reasonably be expected, the most reduced. She has grown thin, pale, weak, and nervous. Menstruation often continues regular, but sometimes diminishes or ceases altogether. The functions of the stomach and bowels are not more interrupted than might be expected from the loss of air and exercise; the appetite is not good, and the bowels require aperients; yet nothing more surely occasions a paroxysm of pain than an active purgative. Such are the leading symptoms of this distressing complaint. To embody them in one view, let the reader imagine to himself a young or middle-aged woman, somewhat reduced in flesh and health, almost living on her sofa for months or even years, suffering from a constant pain in the uterus, which renders her unable to sit up, or to take exercise;—the uterus, on examination, unchanged in structure, but exquisitely tender, even in the recumbent posture; always in pain, but more or less frequently subject to great aggravations.

With regard to the pathology of these cases, Dr. Gooch observes, that the causes, to which this disease has been attributed, are generally considerable bodily exertion at times when the uterus is in a susceptible state; but he remarks, that the patients had previously manifested signs of a predisposition to it. They were all sensitive in body and mind, and many of them had previously been subject to painful menstruation. As to its proximate nature, he is satisfied by stating

that it consists in a morbid condition of the uterine nerves, attended by pain, and sometimes vascular fulness; and he likens it to the irritable breast, the irritable testis, and the painful condition of the joints which is sometimes met with in hysterical females. He does not venture to explain its pathology any farther.

A consideration of the cases of this disease which have come under my notice, appears to me to justify the following conclusions:—

First. That, in the majority of instances, irritable uterus is rather a sympathetic than an idiopathic disease of that organ.

Secondly. That it is sympathetic of irritative disorder of various organs with which the uterus has intimate relations, the irritation of which is reflected, either partially or entirely, upon the uterine ganglia and nerves.

Thirdly. That, whilst such reflected irritation is its immediate cause, it is remotely dependent upon a defective condition of the blood, which would appear to operate by producing a morbidly irritable state of the nervous system generally, and of the uterine ganglia and nerves in particular.

In support of these views I shall quote the following cases.

Case 1. Mrs. E. Nurden applied at the Paddington Free Dispensary, Sept. 20, 1850, suffering from pain in the region of the uterus, increased by standing or walking, and relieved by lying down. The pain radiated from the uterus to the groins and hips, and sometimes extended down the thighs. She had also a good deal of pain in the back and loins, and suffered much from bearing-down of the uterus. The pain varied in intensity, and was sometimes very severe. Menstruation had always been very painful. The os and cervix uteri were very sensitive to the touch, but not otherwise diseased; nor was the uterus displaced. She had suffered from these symptoms for upwards of twelve months. Previously to their accession she had not been in good health; she had been weak, and incapable of undergoing much fatigue. Her tongue had been for some time habitually furred in the morning; her appetite had been bad, her digestion attended with pain, and her bowels confined. She had had a great deal of trouble and anxiety, and was, when first seen, very weak and anæmiated. There was a loud venous bruit in the neck; her tongue was furred, and the digestive organs were disordered. The lower part of the spine was extremely tender on pressure.

The treatment which I recommended had especial reference to the abnormal condition of the blood, the disordered state of the stomach and digestive organs, and the irritable condition of the spine. I directed her to take ten grains of the ammonio-citrate of iron after each principal meal daily, and five grains of blue-pill every second night until the tongue became clean, with sufficient castor oil the following morning to insure a moderate action of the bowels.

October 22nd. She reported herself to be better: she felt stronger, the appetite was better, the tongue cleaner, and her bowels more regular. She had still, however, a great deal of uterine pain, and the lower portion of the spine continued very tender. The dose of the citrate

of iron was increased from ten to twenty grains, and she was directed to rub the lower portion of the spine with an ointment containing tartar emetic and croton oil, night and morning, until pustules were produced.

October 29*th*. She reported herself to be still better. The uterine pain was much less, and her general health was improved; but she had a good deal of leucorrhœa. The ammonio-citrate of iron was ordered to be discontinued; and, in its place, a draught containing fifteen drops of the diluted muriatic acid, twenty of the tincture of the sesquichloride of iron, and a drachm of the solution of bichloride of mercury, was directed to be taken three times a day.

November 26*th*. She was perfectly well. The medicine last prescribed, having agreed with her, had been regularly taken, and the counter-irritation, over the spine, had been also continued. The pain and irritability of the uterus was now entirely gone, as was also the leucorrhœa; her tongue was clean, and the digestive organs healthy. She stated that the counter-irritation, over the spine, gave immediate relief as regarded the uterine pain, which entirely ceased with the improvement of her general health.

Remarks. The circumstances which I have adverted to as productive of the irritable uterus, existed in a marked manner in the present case. The patient was extremely anæmiated on admission, and had probably been so for a considerable period; she had also undergone much mental anxiety and trouble; and these circumstances sufficiently explained the occurrence of dyspepsia, and an irritable condition of the spine, which may be regarded as having been the immediate cause of the uterine derangement. They were certainly antecedent rather than consecutive to it; and the uterine pain disappeared, without any special treatment, under measures calculated to remove them.

Case ii. L. Fross, aged 36, single, applied at the Paddington Free Dispensary, November 26, 1850, suffering from much pain in the uterus, and occasional bearing down. The pain varied in intensity at different times, and occasionally was very intense; it was sometimes relieved on lying down, but was not entirely removed. She had leucorrhœa, which was increased whenever the uterine pain was very severe. Menstruation was regular, but was attended with much suffering, which at times was so great as to make her apprehensive of the existence of inflammation. These symptoms were attended, and had been preceded by general weakness, and a depressed state of the general health. The patient was now extremely anæmiated; a loud continuous bruit was heard over the jugular veins. The tongue was habitually furred, and the stomach and bowels disordered. The lower part of the spine was also tender upon pressure. She stated that she had suffered from uterine symptoms for many years, and that she had consulted several medical men without obtaining much benefit. She was a sempstress by occupation, and had led a very sedentary life. The treatment which I recommended her was principally the following: to take an alterative dose of blue-pill every second night, as long as the tongue was unpleasant on awaking in the morning; to take the muriated tincture of iron three times a day with dilute muriatic acid, and with each dose a drachm of the solution of the bichloride of

mercury; the bowels to be regulated by castor oil, and the spine to be rubbed with tartar emetic ointment, night and morning, until pustules were produced.

December 17*th*. She was much better. The tongue was clean, the appetite good, the bowels regular, and she felt generally stronger. The uterine pain was much less; the leucorrhœa entirely gone. She stated that the uterine uneasiness ceased as the pustules appeared over the spine. She was directed to omit the muriate of iron, and take simply twenty grains of the ammonio-citrate of iron after each principal meal daily.

January 31*st*, 1851. She was perfectly well, and had no uterine pain nor leucorrhœa. The tongue was clean, the appetite good, and the bowels regular. Her menstruation took place a fortnight ago with scarcely any pain.

Remarks. This patient also was very much anæmiated; and, judging from the history of her case, had been so for some time. Again, her digestive organs were disordered, and the spine was tender upon pressure. It cannot, I think, be doubted that these conditions were consequent upon a state of mental anxiety which is almost inseparable from an occupation, which is precarious and ill-requited, and which requires late hours and a sedentary mode of life; and that upon these the uterine disorder had supervened. The treatment, therefore, was addressed to them rather than to the uterine malady; and the result proved that this view was correct. The existence of rather profuse leucorrhœa required special attention; for although it was probably a consequence of constitutional disorder, its continuance would operate unfavourably upon a patient who was evidently anæmiated. On this account the acidulated muriated tincture of iron was given in preference to any other chalybeate: and it had the effect in this, as in many other cases with which I have met, of entirely removing this symptom. The ammonio-citrate of iron was then substituted, in full doses, after each principal meal daily. The result of the treatment tends to show that, in this case, the uterine disorder was a symptomatic affection, inasmuch as it ceased, without any special treatment, on removing the constitutional derangement with which it was accompanied.

Case iii. Mrs. Woodger, aged 36, was seen Nov. 28th, 1850. She was suffering from violent pain in the uterus and left iliac region; she had also pain in the back, and a sensation of bearing-down, or forcing of the uterus. The pain extended to the hips, and sometimes darted down the thighs. It varied in intensity at different times, sometimes being very acute, and sometimes of a more subdued character. On a digital examination, the uterus was extremely sensitive; the slightest touch of the cervix produced great suffering; otherwise it was not perceptibly diseased, congested, or enlarged. These symptoms had been preceded, and were accompanied by a very flatulent state of the bowels, furred tongue, loss of appetite, and other symptoms of derangement of the digestive organs. The patient was also thirsty and feverish, but otherwise her general condition was that of weakness and depression. On inquiring into the history of the case, I found that she had lost her mother twelve months ago; that this had affected her very much; and that she had ever since been in

a nervous bad state of health. In July she had been confined; and, although the labour was easy and natural, and unattended by any unusual hæmorrhage, she had been seized, a fortnight afterwards, with considerable pain in the uterus, evidently of a neuralgic character, which was removed by soothing and sedative measures. The present attack was also apparently neuralgic; and it appeared to depend immediately upon disorder of the chylopoietic organs, together with spinal irritation, whilst remotely it was connected with the painful state of mind, and depression of the nervous system, which had been occasioned by the death of her mother. The indications which I proposed to fulfil, in regard to treatment, were, first, to correct the disordered condition of the stomach and bowels; secondly, to allay the morbid irritability of the nervous system; and thirdly, to remove the spinal irritation. For these purposes she was ordered three grains of calomel immediately, and afterwards the sulphate of magnesia in decoction of aloes and cinnamon-water, at intervals until the bowels were properly opened; to have a linseed-meal poultice applied over the abdomen, and a sinapism over the lower part of the spine, and to take, at bed-time, five grains of Dover's powder.

The next day the pain was lessened; the bowels had been much purged, were less flatulent, and the tongue was cleaner. There was still, however, much uterine pain, and the spine continued very tender on pressure. In consequence of this, the lower part of the spine was ordered to be rubbed with the tartar emetic ointment night and morning, until pustules appeared; and she was directed to take five grains of Dover's powder at bed-time, if in pain, or incapable of sleeping.

In the course of a few days, the spine became irritated by the ointment; and, upon this taking place, the uterine pain entirely ceased, and all that she complained of was weakness and loss of appetite. For this she was given the diluted nitro-muriatic acid, in water, three times a day before meals, and she was ordered a nutritious diet. No other treatment was required from this time. She progressively got better; her appetite improved; she got strong, and has had no return of uterine pain up to the present time.

Remarks. The predisposing cause, in this case, appeared to be the generally depressed state of the nervous system, which was occasioned by the mental uneasiness induced by the death of the patient's mother; and to this state of mind we may, I think, attribute the spinal irritation which was so prominent a feature in the case. Nor can it be doubted that this, together with some casual derangement of the stomach and bowels, was the exciting cause of the uterine malady. The antecedent circumstances of pregnancy, parturition, and suckling, would also favour its occurrence, by weakening the constitution, and rendering the nervous system more susceptible to impression. The ready cessation, however, of the uterine disease on correcting the disorder of the digestive organs and the irritable condition of the spine, proves that it was symptomatic, and that it did not depend upon idiopathic disease of the uterus.

Case iv. Elizabeth Morgan, aged 21, married, but having no children, applied at the Paddington Free Dispensary, suffering from ex-

treme pain in the uterus. The pain extended to the groins and hips, and was always relieved by lying down. The uterus was very sensitive to the touch, but not otherwise diseased. She complained of much pain and dragging at the back, had profuse leucorrhœa, and menstruated every three weeks, but without pain. She had suffered from these symptoms some time; but, before they commenced, she had been out of health. The tongue, for some time past, had been dry and unpleasant on awaking in the morning, although tolerably clean during the day. She had been for some time weak and low, and had undergone much anxiety and trouble. On admission, she was anæmiated and dyspeptic, and the lower part of her spine was tender. The treatment which I recommended her was very simple. I prescribed the muriated tincture of iron with diluted muriatic acid, three times a day, and with each dose a drachm of the solution of the bichloride of mercury. At the same time the lower part of the spine was to be rubbed with tartar emetic ointment, night and morning, until pustules appeared. She continued this treatment for a month, and the entry then made is the following: "Has no uterine pain or uneasiness, no leucorrhœa, and no pain in the back; tongue clean, appetite good, bowels regular." The uterine pain ceased as soon as pustules appeared over the spine, which occurred four days after the commencement of the use of the tartar emetic ointment.

Remarks. The uterine pain appeared in this case to be almost entirely a consequence of spinal irritation, which again was probably due to mental uneasiness. The disorder of the digestive organs was very trivial, and was removed by drachm doses of the solution of the bichloride of mercury. The muriated tincture of iron, in combination with dilute muriatic acid, was given in preference to any other chalybeate, on account of the existence of profuse leucorrhœa.

Case v. Mrs. Ann Dove, aged 40, married, consulted me Jan. 1, 1851, suffering from intense and persistent pain in the uterus and right iliac region. The pain, although constant, was very much aggravated at times. She had been suffering from it for three weeks; and it supervened upon an interruption to menstruation, which was occasioned by her getting wet feet. Previously to this, however, she had not felt very well; and her digestive organs in particular had been very much deranged. The pain was attended by a frequent bearing-down sensation of the uterus, and she experienced great uterine suffering whenever the bowels acted. It was always worse when standing or walking, and better in the recumbent position. She had had profuse leucorrhœa for the last three weeks. The bowels were very flatulent and constipated, and the cæcum was especially distended. The tongue was very much furred, and the appetite bad; she was also feverish and thirsty, and had rheumatic pains in the limbs, which were generally worse at night. The coexistence of febrile disturbance with very marked derangement of the stomach and bowels, led me to direct her to take at once an emetic of ipecacuanha and squills; and, subsequently, three five-grain blue pills, with an interval of six hours between each. She was further ordered to take five grains of the sesquicarbonate of ammonia, and of the bicarbonate and nitrate of potass frequently in water.

On the next day, she was considerably better. The tongue was cleaner; and the pains were generally less in the stomach, uterus, and limbs. The emetic had produced full vomiting, and a large quantity of sour offensive matter had been thrown up. The bowels had acted twice. On the following day she was still better, and, in fact, convalescent; the uterine pain had ceased, the appetite was good, and the tongue clean.

Remarks. This case affords a good illustration of the sympathy which reciprocally subsists between the uterus, stomach, and the constitution at large. A casual interruption of menstruation was immediately followed by great constitutional disturbance of a febrile character, in which the stomach and digestive organs were especially involved; and there is every reason to believe, that the reaction of the latter upon the uterine organs was the cause of that intense uterine pain and uneasiness which were so prominent in the case. By adopting prompt measures for the relief of the chylopoietic disorder, a rapid cessation of the uterine pain was the consequence; and this independently of any other treatment. The case so far is extremely instructive; and, indeed, is rather introduced as illustrative of the general pathology of uterine diseases, than of the form more particularly under consideration.

Case vi. Charlotte Ward, aged 31, applied, November 5th, at the Paddington Free Dispensary, suffering from great pain and bearing down of the womb, with pain and dragging in the back; both were increased by walking or standing, and relieved on lying down. She suffered severely from leucorrhœa, and menstruated every three or four weeks, with much pain. There was a slight prolapsion of the uterus, and the organ was extremely sensitive to the touch, though not otherwise diseased. She had been suffering from uterine derangement for many years. She had had five very difficult labours, each of which had been preceded by marked disorder of the stomach and digestive organs. She had had, also, a great deal of mental anxiety. Eighteen months ago, she had been prematurely delivered of a still-born child; and the immediate cause of this was fretting and trouble. Her tongue was, and had been for some time, habitually unpleasant; the appetite was bad; and the bowels were scantily relieved. The lower part of the spine was very tender on pressure. She had been in very bad health ever since her marriage, in consequence of extreme anxiety. The first effect of this upon her constitution, was disorder of the stomach and digestive organs; and upon this uterine derangement soon supervened. She was now very weak and anæmiated, and had a distinct venous bruit in the neck. I prescribed for her ten grains of the ammonio-citrate of iron, and five of the sesquicarbonate of ammonia, in water, after each meal; also five grains of blue pill every night for three nights; and directed the lower portion of the spine to be rubbed night and morning with the tartar-emetic ointment until pustules appeared.

November 7. She felt better. The tongue was cleaner and more pleasant; the appetite better. The spine had been a good deal irritated by the ointment, and the uterine pain was much less. The leucorrhœa,

however, continued very great. She was directed to discontinue the use of the ointment; to take a blue pill every second night; and to substitute for the ammonio-citrate of iron, a mixture containing the muriated tincture of iron, with diluted muriatic acid and a solution of the bichloride of mercury.

November 18. She was much better and stronger. The tongue clean, and the bowels regular. The leucorrhœa was quite gone, and she had very little pain in the uterus. She was directed to continue the medicine.

December 3. She reported herself quite well; and was accordingly discharged, cured.

Remarks. The principles upon which this case was treated are sufficiently clear from the narrative. The patient, prior to the commencement of uterine derangement, had been very much out of health. She had been weak and low, had been suffering from disorder of the chylopoietic organs, and had been prematurely delivered of a still-born child, doubtless the effect of weakness and general ennervation. All this had been preceded by great mental uneasiness; and this would account for the irritable state of the spine, which was so apparent when the patient was first seen. It was probable, moreover, that the uterine disturbance depended upon this, together with the disorder of the digestive organs; and this view, which was suggested by the history of the case, was confirmed by the results of treatment. The remedial measures were exclusively addressed to these conditions; and, on correcting them, the uterine malady disappeared without any special treatment whatever. This case tends strongly to shew that uterine disease, however severe or long continued, is for the most part symptomatic; and that it can only be successfully dealt with, by carefully attending to those remote causes in which it has originated.

Case vii. Margaret Nadauld was seen by me, October 1, 1850, suffering from very intense pain in the uterus and left iliac region. The pain was of a very excruciating character, was increased by the least pressure over the uterus, and the slightest touch of the cervix was followed by great suffering. There was, moreover, a great deal of febrile disturbance, a quick pulse, hot skin, furred tongue, thirst, and disordered bowels, The lower part of the spine was very tender; and, on pinching up the skin of the left iliac region, the patient evinced a good deal of distress. The case so far was clearly neuralgic; and, on investigating its history, there was every reason to believe that it had originated in a fright which the patient had had a few days before. She was directed to have a linseed meal poultice applied over the hypogastrium and left iliac region, and a sinapism to the lower part of the spine. One grain of calomel, and five of Dover's powder, were to be taken every four hours, until three doses had been taken; and, on the following morning, as much castor oil as would insure a full action of the bowels.

The next day, the symptoms were all abated; and, so far as the immediate attack was concerned, the patient considered herself to be convalescent. I was, however, again consulted by this patient a few weeks afterwards, on account of general bad health, and chronic uterine disease. It appeared that she had been for many years in

indifferent health, that she had been weak and nervous, and had suffered more or less frequently during this time from pain and uneasiness in the uterus, especially when walking or standing. A digital examination did not reveal any sufficient cause for the pain; the position of the womb was natural, but the cervix was extremely tender to the touch. She had had a severe labour twenty years before, and thought that the womb was then injured, as she had never been quite free from uterine uneasiness since. She suffered very much at each menstrual period, and was sometimes confined to her bed in consequence. She had no leucorrhœa. The lower part of the spine was still painful on pressure, the tongue and digestive organs were disordered, she was thin and anæmiated, and there was a loud venous murmur in the neck. She had gone through much anxiety and trouble, and for some time past had been living very low. She was ordered to take ten grains of the citrate of iron, and five of the sesquicarbonate of ammonia, in water, after each meal; to take five grains of blue pill every second night, until the tongue and digestive organs were healthier; and to rub the lower part of the spine with the tartar emetic ointment, night and morning, until pustules appeared. This treatment was continued for about a month, and she then reported herself quite well. The entry I made is the following: "Is quite free from uterine uneasiness. The ointment produced a good deal of irritation; and ever since she has been entirely free from uterine pain or bearing down." This, she says, "has not been the case for twenty years."

Remarks. This report contains in reality the history of two distinct forms of uterine disorder; the one an attack of acute uterine irritation, attended by much constitutional disturbance and fever, and immediately occasioned by fright or severe mental agitation; the other that of a chronic form of uterine neuralgia, dependent upon derangement of the general health, anæmia, disorder of the stomach and bowels, and spinal irritation. When called upon to see the patient in the first instance, I had no previous acquaintance with her, and my attention was entirely directed to the relief of her acute sufferings. These subsided quickly, under the treatment adopted; and some weeks subsequently elapsed before I was again consulted by her. I then learnt that she had for many years suffered from chronic uterine disease, which, no doubt, had predisposed to the more acute attack for which I had previously attended her; and this is so far important, as showing that, when such predisposition exists, any occasional cause, such as sudden fright, shock, or emotion, may light up such a degree of irritative disorder and consecutive febrile disturbance, as it would be difficult otherwise to account for. The treatment in both instances was conducted upon principles which have been frequently adverted to, and therefore need not be enlarged upon.

Case viii. Jane Tresey, aged 26, single, applied to me for advice, suffering from pain in the uterus, back, and loins, bearing down, and at times intense suffering in the womb. She had, also, leucorrhœa; and, although menstruating regularly, had much pain at each monthly period. Her digestive organs were a good deal disordered, and she was weak and anæmiated. She had been suffering from these symptoms for a twelvemonth. She had previously been out of a situation,

and had in consequence become anxious and uneasy. This was soon followed by derangement of the digestive organs, and subsequently by uterine uneasiness and leucorrhœa. The spinal column was not examined. She was directed to take ten grains, increased to twenty, of the ammonio-citrate of iron, after each principal meal; and five grains of blue pill at bed-time, when the tongue was unpleasant on awaking in the morning. This treatment was continued for three weeks; and, in addition, she was directed to sponge the lower part of the back with cold salt and water night and morning. At the end of this time, she was better in every respect. She had no uterine pain nor leucorrhœa; the tongue was clean, the appetite good, and she felt altogether very well.

Remarks. This was a simple case of irritable uterus, arising from disorder of the general health, not very protracted, and therefore not difficult of cure. An impoverished state of the blood, with its usual consequence, dyspepsia, appeared to have been its sole cause; and the mere exhibition of steel in full doses was sufficient to accomplish the cure. The leucorrhœa ceased with the irritability of the uterus, shewing that, if it did not depend upon it, it had at least a similarity of origin. This, in fact, will be found to be frequently the case. Irritation of the nerves of an organ is generally followed by increased secretion, either from it, or some other with which it is sympathetically allied: this indeed is a mode of relief which is often spontaneously set up by nature, and, in proportion as it takes place, are suffering and disorder alleviated. To regard it, therefore, under such circumstances, as a disease which should be immediately checked, would be unsound in principle, and fraught with danger in practice; whilst, on the other hand, the removal of its remote causes is often followed by its spontaneous cessation, as shewn in the present case.

Case ix. Sophia Wheeler, aged 33, applied at the Paddington Free Dispensary, suffering from pain in the uterine region, more or less constant, but liable to severe exacerbations every two or three days. She had also great pain in the back and loins, and profuse leucorrhœa. She had laboured under these symptoms for many years. On a digital examination, the cervix was found to be extremely tender, but the uterus was not prolapsed, nor presented any unnatural condition, except a little puckering and irregularity about the os. Menstruation had been regular until her late pregnancy, but had always been attended with much pain. She had been confined five months ago, and had menstruated twice since. She had six children, and had suffered much from hæmorrhage at each birth. She was never very strong, or equal to much fatigue, and for years had suffered greatly from anxiety. The tongue had been also for many years very much furred and unpleasant in the morning; her digestion bad, and her bowels confined. She was extremely weak and anæmiated; and there was a loud venous bruit in the neck. The tongue and digestive organs were very much out of order. The spinal column was morbidly tender in various parts, and she was nervous and hysterical. She was ordered the muriated tincture of iron with muriatic acid, and the solution of bichloride of mercury in infusion of serpentary, three times a day; a blue pill at bed-time occasionally, and the

tartar emetic ointment for the spine. The treatment, however, was not long continued. The patient, at the time of attending, was in so much trouble and distress, that it was useless to expect much benefit from medicine—a circumstance which I pointed out to her. She therefore discontinued her attendance; but the case is instructive, as pointing out the existence of those forms of constitutional derangement, which have been remarked to be the cause of uterine disorder.

The last case I shall quote is that of a farmer's wife, who came from a considerable distance in the country to obtain advice in London. She had been for many years a severe sufferer from uterine disease, and had been treated by many practitioners without any benefit. Whether the treatment I recommended was serviceable or not, I have no means of judging, as I only saw her on the occasion of her consulting me.

Case x. Mrs. A. H., aged 37, was seen November 16, 1850. Her symptoms were severe pain in the uterine region, more or less constant, but very much worse at times, and much pain in the lower part of the back, extending round to the uterus, and darting down the thighs. She had had this pain about nine years. It was preceded by great mental anxiety, and by a miscarriage, which was brought on by jumping off a gate, and this was followed by considerable hæmorrhage. Ever since, she had been very much out of health; she had scarcely ever been free from uterine pain, which was always increased by walking or standing. The digestive organs had been throughout disordered; the tongue habitually unpleasant of a morning, and it was now much furred at the back. The spine was altogether very tender, but more particularly its lower portion, and the skin of the left flank was morbidly sensitive to the slightest touch. There was a loud venous murmur in the neck, and the patient was weak, nervous, and much depressed. She had been under the treatment of several medical men, who had each taken a different view of her case. By one she was said to have inflammation and ulceration of the cervix uteri, and she was cauterised for a long time, and leeches were applied to the uterus, but without any benefit. On a digital examination, the cervix was exquisitely tender, so that the slightest touch gave extreme pain, but it was not otherwise diseased. On the anterior part of the uterus, there was a distinct enlargement, probably fibrous. The axis or direction of the cervix was normal, and the only perceptible lesion was the extreme sensitiveness of the organ. The patient was regular, but menstruated with great pain. She had no leucorrhœa.

The uterine symptoms having been preceded by mental anxiety and much loss of blood, the spine being very tender, the digestive organs disordered, and the blood evidently impoverished, I was led to consider these circumstances, in the absence of any appreciable disease of the uterus, as furnishing the principal indications of treatment. I recommended the patient to have the spine rubbed night and morning with the tartar emetic ointment until pustulation was produced; to take five grains of blue pill every second or third night, as long as the tongue was furred; to regulate the bowels by mild aperients; and to take the citrate of iron after each meal, increasing the dose gradually from ten to twenty grains; to live well, and to adopt such a regimen

as was calculated to improve the general health. As I have before said, I have not seen the patient since, and therefore I do not know the result of the treatment. I had a note a few days after my interview with her, informing me that the ointment had produced a very angry eruption; a circumstance which would tend to show that the blood was not only impoverished, but bad; and so far to confirm the correctness of the view which had been taken as to the sympathetic origin of the uterine affection. At all events, the coexistence of spinal irritation, irritative disorder of the digestive organs, and anæmia, with uterine disease, was very evident in this case, whatever may have been their mutual relations.

General Remarks. Upon a general review of the preceding cases, the first inference I would venture to draw from them is, that they are affirmative of the truth of the propositions which were advanced at the commencement of this paper. In all, the uterine affection appeared to be consecutive to, or sympathetic of, constitutional derangement or irritative disorder of other organs. In none could it be regarded as dependent upon idiopathic disease of the uterus; and additional corroboration is derived from the fact, that it disappeared, in most instances, under the influence of treatment of a general rather than of a specific character.

Another inference which may be drawn from them is, that the influence of gastro-intestinal disorder and spinal irritation are very considerable in the causation of uterine derangements. In the majority of the cases reported, these coexisted, and would seem to have had a similarity of origin. In all, they were associated with anæmia, and had been preceded by much mental anxiety. How much, therefore, is due to each in the production of the uterine symptoms in these cases, it is impossible to say. Many circumstances, however, which have come to my knowledge, lead me to believe that derangements of the uterus, involving more particularly its nutritive and secretory functions, such as leucorrhœa and disorders of menstruation, have rather a gastro-intestinal origin when sympathetically induced; whilst those which affect more particularly its sensory functions, producing neuralgia, and various irritable conditions, are for the most part connected with an irritable or morbid condition of the spinal cord.

But it is not contended, that hysteralgia is in all cases necessarily connected with either spinal irritation, or gastro-intestinal disorder. I believe them to be very frequent causes, but I have met with instances in which it existed irrespectively of either. In gouty and rheumatic subjects, considerable uterine pain, more or less of a persistent character, is often met with, doubtless of a gouty or rheumatic nature; and I believe that severe irritation of any important organ or nerve may, under certain circumstances, be reflected upon the uterus, so as to give rise to very distressing symptoms. In illustration of this, I will quote the following case, which was published by Mr. Davis in the *Lancet* of August 1, 1846, page 125.

A patient, six days after labour, was attacked with severe pain, of an intermittent character, in the region of the uterus, and during the intermissions she had pain in the face. Leeches, fomentations, etc., were applied to the abdomen, and calomel and opium were given in-

ternally, but without avail. At length, the pain in the face becoming more severe, inquiries were made, which led to the discovery that one of the dentes sapientiæ was coming up, and causing inflammation and swelling of the gum. A free incision was accordingly made in the swollen gum, and an entire cessation of the uterine pain immediately followed, without any other medicine being given.

In this case, we have an instance of uterine pain arising from a peculiar but by no means unusual cause; and it may be a question whether some of the neuralgic affections of the uterus, which occur in young females, may not depend upon it. Every one is aware of the sympathy which subsists between the nerves of the uterus and those of the teeth; and that consequently, during pregnancy, tooth-ache is a frequent occurrence. I am not, however, aware that this is considered to be reciprocal, although the present case would prove it to be so certainly. As regards many other sympathies, I have reason to believe that such is the case, and that the uterus as fully sympathises with morbid conditions of particular organs and the constitution at large, as do these with abnormal or peculiar conditions of the uterus.

In further illustration of the pathology of these affections, I have made the following analysis of thirty-seven cases, in which the uterus was in a morbidly irritable state, not in consequence of displacement or appreciable disease. In all there was marked pain and uneasiness in the region of the uterus, which varied in intensity in different instances, and in some had been of long continuance.

I. UTERINE COMPLICATIONS were observed in the following proportions.

In	3	there was no other uterine disease.				
„	15	the pain was complicated with leucorrhœa.				
„	7	„	„	„	„	leucorrhœa and dysmenorrhœa.
„	3	„	„	„	„	leucorrhœa and amenorrhœa.
„	1	„	„	„	„	leucorrhœa and menorrhagia.
„	4	„	„	„	„	leucorrhœa and irregular menstruation.
„	4	„	„	„	„	dysmenorrhœa alone.
„	2	„	„	„	„	menorrhagia.
„	1	„	„	„	„	fibrous enlargement of the neck of uterus.

II. ANTECEDENTS. The irritable state of the uterus had been preceded,

In	4	cases,	by weakening discharges, such as profuse hæmorrhage, and protracted suckling.
„	5	„	mental anxiety and distress.
„	8	„	mental anxiety, with disorder of the digestive organs.
„	2	„	sudden fright.
„	18	„	disorder of the digestive organs.

III. CONCOMITANT AFFECTIONS.

In	18	there was	well-marked anæmia, with disorder of the stomach and digestive organs.
„	12	„	anæmia, with spinal irritation.
„	3	„	spinal irritation.
„	4	„	great irritability of stomach and digestive organs.

The facts, contained in the foregoing analysis, appear to me to justify the following conclusions:—

First. That, from the operation of the same causes, various and dis-

similar uterine diseases may be occasioned. Thus the principal antecedent circumstances in these cases were, for the most part, the same, and yet very different disorders were the consequence. In some, there was simply a painful condition of the uterus; in others this coexisted with leucorrhœa, amenorrhœa, dysmenorrhœa, menorrhagia, etc. The probable explanation of this is, that the operation of the different causes in question is primarily upon the nerves of the uterus, and that irregular actions, in regard to these, precede and give rise to those particular symptoms, which, in the aggregate, constitute disease as known by a given appellation.

Secondly. That, all these lesions may arise from constitutional disorder, may be perpetuated by it, and in many instances will cease on its removal. In these cases the chief circumstances which had preceded were either of an enervating or depressing nature; such as loss of blood, over-suckling, etc., or mental depression or uneasiness. The obvious effect of these would be to lower the tone of the nervous system generally, and to render it morbidly susceptible to impression. Thus it would happen in regard to the uterine ganglia and nerves, that they would be prone to irregular actions, and to participate readily in the morbid affections and conditions of other organs. If, again, the impressions leading to such abnormal actions are received from or through the medium of the ganglionic system of nerves, it is reasonable to suppose that the functions to which these are more immediately subservient, such as nutrition and secretion, would be more particularly disturbed, whilst those received from or through the medium of the cerebro-spinal system would rather give rise to painful and uneasy feelings; and thus may arise the difference in the uterine derangement which is consecutive to chylopoietic disorder and spinal irritation.

I am well aware that many of the cases of irritable uterus, which have come under my notice, and have been alluded to in this paper, were comparatively slight, as well as of recent occurrence, and therefore proportionately more amenable to treatment. I have, however, in no instance included under this title cases which were not attended by well marked pain and suffering in the uterus, bearing-down of the organ, and other uterine symptoms, irrespective of inflammation, displacement, or appreciable disease. In all, the general condition of the patients was that described by Dr. Gooch. They were nervous and hysterical, weak, and generally out of health; and the uterine pain appeared to be neuralgic. On the other hand, the cases which he has related were of a very confirmed and aggravated character; but, so far as I can judge from his account of them, they do not militate against the views which I have expressed, whilst the results of the treatment adopted tend rather to confirm them. In all the cases of irritable uterus which I have seen, the patients were, as I have stated, weak and enervated, depressed, and more or less anæmiated from the commencement; and treatment of the most invigorating character was, from the first, had recourse to, with the greatest benefit. Dr. Gooch's cases also appear to have been of the same description, but in which very opposite treatment had been adopted.

The first was that of a young lady who married at twenty-four, and, after her first confinement, went to a fashionable watering-place, and

there passed a winter of *laborious gaiety;* her mornings being spent in making calls, and her evenings in standing in crowded parties. *She lost her appetite, suffered much from languor, and became subject to shooting pains at the lowest part of her abdomen.* In consequence of an accession of pain, and a sense of fulness in the womb, she applied leeches, lived low, and was confined to her sofa several weeks. At the end of this time she was supposed to be well; but subsequently she had a violent relapse, attended with great pain and tenderness across the lowest part of the abdomen. From this time she appears to have been a great sufferer, and to have undergone very heroic treatment. She was bled four times in one week; blood-letting, either general or local, was afterwards repeated from time to time, and mercury was given to salivation. All this was done with very doubtful advantage, and her eventual recovery, after a protracted period of suffering, appeared to have been connected with the improvement of her general health, and a very cautious mode of living; but it is surely not too much to say that the treatment adopted, in the early stage, was calculated to impair very materially the tone of the nervous system, and to convert an ordinary neuralgic affection into one of very great severity.

The second case was that of a patient, who, when seen by Dr. Gooch, was so emaciated that he could encircle her arm by his thumb and middle finger. Her complexion was like wax; her digestive organs were very much disordered; so much so, that of every meal she brought up a portion; and her bowels never acted without medicine. Her pulse was small, weak, and quick, and easily quickened by the slightest motion. She had also profuse leucorrhœa. These circumstances surely indicated the existence of anæmia in a severe form; and yet blood-letting was one of the principal measures which had been had recourse to. Leeches had been applied, on an average, ten times a month; and if, as it is stated, the quantity of blood, drawn at each time, is estimated at two ounces, she must have lost about twenty ounces every month, and this while she was taking very little nutriment, and of that little rejecting a large portion. It is further stated, that the paleness of the blood, and the marble-colour of her face and skin, showed how the circulating fluid had been drained of its red particles. Such was her condition when she arrived in London, nearly twelve months from the commencement of her illness; and can it be a matter of surprise, after such treatment, that her nervous system generally was in a highly sensitive condition, and that the irritability of the uterus had become very great?

The third and last case mentioned is that of a young woman, who had borne four dead children, and therefore presumptively had not been very strong. Hæmorrhage had occurred after the last confinement, and was succeeded by pain in the hypogastrium and left iliac region. Her pulse is described as being small and wiry; a very common pulse, it is observed, after hæmorrhages from the uterus. The narrative informs us, that she was now bled four times in less than a week; that she lost in this time eighty ounces; that a number of leeches were applied to the hypogastrium repeatedly, and that, when seen a week afterwards, her face and lips were bloodless, her health broken, and that she had the local symptoms of irritable uterus, —it need not be added, in a very severe form.

Looking to the report of these cases generally, and their probable nature and origin, and observing the treatment respectively adopted in each, I confess I cannot feel surprised at their extreme severity. The existence of anæmia, weakness, and prostration, both antecedently to the attack, as well as concurrently with it, is conclusively shown, although the relation of these to the disease appears to have been altogether overlooked. Under such circumstances, what could have been expected from active depletion but the results which followed,—viz., increased anæmia, and a correspondingly greater irritability of the nervous system, more especially of those portions which were previously in a morbidly irritable condition?

Had the cases I have reported been treated in the same manner; had the patients to whom I have referred as suffering from irritable uterus, and who, together with this, were evidently weak, dyspeptic, and anæmiated, been bled frequently to the extent mentioned by Dr. Gooch; had they, in addition, been mercurialised, kept sedentary, and restricted in diet,—can it be doubted that their sufferings would have been proportionately increased? and that an irritable condition of an organ, otherwise slight, would have been rendered equally unmanageable and severe?

The practical conclusions, then, which I would venture to draw from the cases of this disease which I have myself seen, as well as from those reported by Dr. Gooch, are the following. In every instance of hysteralgia, or irritable uterus, it is absolutely necessary to look beyond the condition of the uterine organs for an explanation of the origin of the disease; to inquire particularly into the condition of the blood, and to ascertain how far it is either defective or excessive, or how far it is deteriorated by the prevalence of any particular diathesis, such as the gouty or rheumatic; to ascertain whether irritative disorder exists in organs which have sympathetic relations with the uterus, and to carefully investigate the condition of the brain, spinal cord, the nerves, and the nervous system generally. Such an investigation will often lead to the discovery of the causes of uterine irritability, where otherwise they would be overlooked; and will best furnish the principles upon which the treatment of the disease should be conducted.

Chester Place, Hyde Park Gardens, March 1850.

HINTS ON SOME RELATIONS OF MORALS AND MEDICINE,

WITH SPECIAL REFERENCE TO PULMONARY CONSUMPTION.

By THEOPHILUS THOMPSON, M.D., F.R.S., Physician to the Hospital for Consumption and Diseases of the Chest.

(*Read before the Medical Society of London, February* 15, 1851.)

THE object of this communication will be best secured by presenting, in the first place, a few simple and brief considerations regarding some of the principal Causes of Pulmonary Consumption.

The first of these causes is *hereditary influence*. There is, perhaps, no disease in which this influence is better established; and it peculiarly claims attention, in consequence of its power to perpetuate the effect of causes which might otherwise prove temporary, and restricted to the individual exposed to their agency. In more than a thousand patients examined at the Brompton Hospital, in reference to this subject, about a fourth had lost a parent from consumption. This mode of origin was traced about twice as frequently in the women as in the men; and it is worthy of observation, that the influence tends peculiarly to extend in the direction of the sex in which it first appeared. Of thirteen women at present under my care, whom I have questioned carefully on this point of inquiry, three have lost both father and mother, two their mother only, one the father alone. And this statement represents, on a small scale, the conclusions deduced from more extended statistical inquiry.

Secondly, no one will doubt that the influence of *bad air* must tend materially to the production of phthisis; and, assuming this to be the case, I may specify tailors, journeymen bakers, and printers, as likely to suffer in a high degree. Tailors constitute a large proportion of the patients at the Brompton Hospital—not less than 7·2 per cent. They are, unhappily, liable to many other diseases, and constitute about 5·8 per cent. of the patients of a general hospital. A class, representing but a small proportion of the male population, must be exposed to very unfavourable circumstances, to be rendered in so high a degree prone to disease. Journeymen bakers are subject to complicated causes of disease;—work prolonged for twenty hours; gas-light instead of sunshine; hot gusts of flour-dust instead of the fresh air:—and of the journeymen bakers in this metropolis, probably a fourth have symptoms of phthisis.

The next class to which I would allude is printers. Although it is probable that the number of printers in this city is not above one third as great as that of tailors, their per-centage is half as many in our list of applicants at the Hospital for Consumption; and their liability to consumption appears to be four times as great as to other diseases. But there is an important fact connected with the liability of printers, for the knowledge of which we are mainly indebted to the meritorious

investigations of Dr. Guy, a physician entitled to the best thanks of the public for his laborious inquiries. The fact is, that the liability of pressmen and compositors materially differs. During a long period of observation, it was ascertained that, whilst the proportion of pressmen applying at King's College Hospital, who were consumptive, was one-fifth, that of the compositors amounted to one-fourth. The wages of the compositor being higher, and his habits fully as temperate as those of the pressman, we have to seek the cause of his greater proneness; and the obvious explanation would seem to be the want of the exercise which, in the pressmen, may be supposed in some degree to counteract the effect of confined air. This opinion derives confirmation from the observations made some years since by Lombard and Benoiston, on the effect of exertion of the arms in counteracting a tendency to phthisis.

The third cause, at which I shall only glance, is *dissipation*. The depressing influence of this cause will be readily acknowledged. To syphilis and mercury I have repeatedly traced the first origin of consumptive disease. In the majority of the male patients at present under my care, this influence seems to have had a considerable share in the production of phthisis. This leads me to notice a remarkable fact, as regards the liability of soldiers to consumption. Even the Dragoon Guards, who are more favourably circumstanced than many divisions of our army, exhibit annually a mortality of ·63 per cent., whilst that of the male population of England and Wales is only ·37 per cent. At first sight, it is probable that the cause above referred to would be suggested in explanation; and I am ready to acknowledge that our gallant soldiers, although above fear, are not so constantly as we would desire above reproach. But this explanation proves inadequate, when we reflect on the comparative immunity of sailors from the disease; and I cannot but attach importance to the explanation suggested by Dr. Duncan, viz.: "The listlessness of their life, and the dull monotony of drills and parades." (*Dublin Medical Journal*, vol. ix, p. 32.)

I am thus conducted to a branch of the inquiry, to which I am specially anxious to invite attention; namely, *the effect of mental impressions in predisposing to phthisis*. We are apt to forget the remarkable influence of emotion in modifying respiration; but, if any one will observe his breathing when any depressing subject is dwelling on his mind, he will soon be convinced of the tendency of such depression to retard the respiratory act. The terms breathless anxiety, breathless suspense, are not mere metaphors. The idea implied in these popular expressions is forcibly introduced by the patriarch Job, chap. ix, verse 18: "He will not suffer me to take my breath, but filleth me with bitterness":—and it may not be inappropriate to suggest how aptly this passage illustrates the fact that, while the language of inspiration is preeminently adapted for conveying truth, not to philosophers alone, but universally, even to the untutored multitude, it nevertheless, on occasions consistent with this principle, combines in a remarkable degree scientific accuracy with general comprehensibleness.

Inasmuch as mental depression may interfere with digestion, it may

lead to various maladies; but by retarding respiration, and thus inducing pulmonary congestion, I believe it specially tends to promote the deposition of tubercle.

It is not improbable that such an explanation may be applicable to a common condition of the recluse student, and the man of refinement, who shrinks from the busy scenes of active life, and, worn with cerebral labour, is "sicklied o'er with the pale cast of thought".

The medical statistics of our prisons afford striking illustrations of moral causes of disease. Dr. Baly has shown, from extensive observations of prisons in various parts of the country, and in America, under great varieties of climate, diet, and general regulation, the prevalence of one common circumstance,—namely, greater liability to consumption than exists among the population generally; amounting, in the case of the Millbank Prison (where, however, it must be acknowledged that a combination of unfavourable circumstances are in operation), to about four times the average; the time required for the full development of the effects of the unfavourable influence being about three years.

An interesting question arises, whether the causes referred to in this communication are equally influential with both sexes. The statistics which I have at command indicate a considerable difference. In London, the mortality of women from phthisis is much less than that of men, and the advantage is specially observed in married life; the proportion of the female cases to the male, under such circumstances, over the age of twenty-five, being as three to five. This remarkable fact can scarcely be due to other than moral causes; and such are easily assigned. Man, in struggling for the support of his family, is beset with anxious care; woman, with more faith and patience, provided she receives her just share of consideration and tenderness, fulfils cheerfully the duties of the day, and does not so anxiously regard the morrow.

The records of the Registrar-General supply, as it seems to me, an additional confirmation of this view, in the remarkable fact, that the mortality in some provincial cities, as well as in the metropolis, is least for women; but that in the counties the proportion is, in a higher degree, to the disadvantage of the female. The only important exception to the rule, as respects provincial cities, is Leeds, in which the excess of female mortality is equal to that in the kingdom generally. I know not how these facts are to be explained, except by some peculiarities of moral condition. As a test of this condition, it has occurred to me to examine the Registrar-General's return of the number of illegitimate children born respectively in certain districts which I had previously noted, as illustrating the fact just specified.

The order of increase, in the proportion of female mortality, is exhibited in the following table of the per-centage of deaths observed, in each instance, on 200,000 of the population, as deduced from the Registrar-General's return for the year 1837.

I have given, in an additional column, the per-centage of illegitimate children in relation to the whole number of children born; and although the returns, in this respect, are unavoidably for a different year, the relative proportion of different places for several successive years sufficiently corresponds to obviate any incidental fallacy.

	Deaths from Phthisis.		Proportion of illegitimate children to children born.
	Men.	Women.	
London	·455	·377	3·2 per cent.
Liverpool and West Derby	·595	·571	3·6 —
Manchester and Salford	·549	·548	5·8 —
Leeds	·440	·477	6·0 —
England and Wales	·378	·408	7·0 —
Paris, according to Benoiston ..	·288	·480	28·0 —

It is not intended to imply merely that the mothers of illegitimate children are peculiarly prone to phthisis, but that, in districts where the proportion is high, such a system of morals may be assumed to prevail as must extensively expose the female population, in a marked degree, to causes of moral disquietude. The return from Paris, even admitting some deduction on the ground of large Foundling hospitals, is remarkably high; and the female mortality of that metropolis, from phthisis, is not less striking. It will scarcely be disputed that, in any district notorious for the number of children born out of wedlock, there will the women be least happy in condition, most exposed to hope deferred, unrequited affection, bitter ingratitude, and all the causes which tend to wither the heart of those whose life may be said to ebb and flow with their emotions. If the power of mental causes to induce such disease were disputed, many instances might be adduced in support of my opinion. Let one suffice. In some parts of Wales a superstition still prevails that, if the image of any individual be put into one of the charmed wells, as that image melts away, the person represented will pine and die. A beautiful young woman had refused to marry a dwarfish and almost idiotic neighbour. The mother of the young man used every solicitation on his behalf in vain, and then, in revenge, declared she would put the image of the obstinate girl into the well. The poor girl credited the superstitious tale, and soon fell ill. An eminent physician, to whom I am indebted for the narrative, watched her with interest, prescribed for her symptoms, and strove to dispossess her mind of the idea which so painfully beset her, but in vain. There was no hereditary tendency, nor any other explanation of the origin of the disease; but phthisis distinctly manifested itself, and in six months she died.

Impressed as I am with the conviction, that depressing moral influences often induce consumption, I am not less persuaded that cheerful impressions tend to retard the disease. I have long observed that the patients improve more rapidly, and that the mortality is less, in the large than in the small wards of the Brompton Hospital, although the space allowed is proportional to the number of patients admitted into them; a result very different from that which we observe in diseases associated with morbid poisons, and even in some epidemics, especially influenza, in which the existence of such virus is disputed. The influence of cheerful society I have particularly observed amongst the female patients. And here I would remark, that women, from some peculiarity of constitution, bear confinement to the house in phthisis, and other diseases, better than men; whilst with men, horse exercise, and other muscular exertions out of doors, are more obviously useful,

and the evil of confinement is often greater than the risk of moderate exposure, even at a somewhat advanced period in the progress of disease.

Of the causes thus cursorily illustrated, as tending to induce and aggravate phthisical disease, some are under our own control.

First. The air of our apartments and workshops is not by necessity a contaminated air; open fire-places, with Arnott's ventilators, or a zinc-pipe, or some other simple precaution, will, to a great degree, correct the evil, and some hundred lives would thereby be saved annually in this metropolis alone. If the proportion of deaths from phthisis, among the artizans in London, were reduced to that which prevails among the gentry, fifteen hundred lives, at least, would be annually saved in this metropolis. No physical advantages can compensate for the evils incident to contamination or exclusion of light, air, and water. Vanity and ignorance may affect to regard disease as an exotic, but it is a narrow view to expect to exclude, by quarantine, diseases which close workshops can engender. A suspected ship is not so bad as a convicted house, in which not only sudden epidemics, but ailments still more destructive, although chronic, so readily originate.

Secondly. In addition to the use of free muscular exercise in the open air, great advantage would be derived from attention to the power with which the will is endowed over the respiratory muscles. And I cannot but believe, that some of the evils of close application to study would be obviated by occasionally pausing to practise breathing. On this subject I should be tempted to enlarge, were it not that the principle rests on physiological truths, which were well elucidated in a paper read to the Society by Mr. W. F. Barlow in the spring of 1849.[1]

Thirdly. It is the duty of the medical practitioner to take every opportunity of impressing principles imperfectly appreciated, but of great importance in relation to the production of consumption, and to place his influence in opposition to that inordinate estimate of lucre, which leads so many to forget that health is property of the highest value. He should enforce the truth, that ambition, disproportioned to power, is a constant source of physical exhaustion and moral disquietude; that it is difficult to calculate the amount of advantage which individuals would derive, if they would study to attain a correct estimate of their powers, and not engage in labours to which they are not adapted; and that health, as well as happiness, would be essentially promoted, if education were habitually conducted so as to train the mind for tranquil superiority to passing cares, and to fit for the exhilarating occupations of a useful life. Physical suffering is, in a great degree, attributable to ignorance or neglect of laws which are displayed for our instruction, and established for our advantage. And, as a general rule, it may safely be asserted, that "to be morally right is to be physically happy".

3, Bedford Square, February 1851.

ON THE STATE OF MEDICINE AMONG THE BURMESE.

By E. A. PARKES, M.D., Professor of Clinical Medicine, in University College; Physician to University College Hospital, etc.

(*Read before the University College Medical Society, in March* 1848.)

Every one engaged in the practice of medicine, all who have experienced the difficulties which encompass the treatment of the majority of diseases, must have felt a desire to know something of the state of medicine among other nations, and particularly among those who are removed from the influence of European literature and civilisation. We naturally wish to know what is thought of a disease by those who are not learned in our pathology, nor trained in our methods; we wish to note the success of the treatment which has not been dictated by the traditions of our schools, and which may possibly not be in accordance with our theoretical explanations.

And, apart from this natural curiosity, the imagination always conceives that, among the people inhabiting the central regions of the earth, among whom civilisation first arose, there may yet linger some traces of that antique and sublime philosophy, which gave its faith and its religion to Egypt, its poetry and its philosophy to Greece. In this hope, the medical science of the Hindus has of late years been fully studied; and if it has not been found to justify all the expectations which were entertained respecting it, still full justice has not, as I conceive, been done either to its philosophy or to its practical application. Not to its philosophy, because the mind of the European, energetic, practical, rapid in induction, and trained for some centuries in the employment of a rigid and logical method of thought, cannot appreciate the minute, subtle, half-mystical intellect of the Hindu; an intellect, perhaps never grand, colossal, and imposing, but peculiarly pliant, rapid, penetrating, and acute. Not to its practice, because the European has perhaps not sufficiently estimated the influence which climate and locality, peculiarities in living, and modes of existence have upon diseases. And the standard by which the opinions of the Hindu physicians, and, to go down to a later date, of the Arabians, and particularly of Avicenna, have been judged, has been exclusively European:—as if locality and modes of life, which from one primitive type can effect so wonderful an alteration in the man's external traits, which can originate the projecting lower jaw, wide nostrils, dark skin, and woolly hair of the Negro; the long dark hair, the square head, and narrow oblique eye of the Tartar; or the regular oval face, straight nose, and light skin of the Asian variety, would not also exert an immense influence in altering, to a certain extent, the type of a disease, and in appreciably influencing the reaction of the body on a morbid poison.

I do not wish at the present time, however, to enter into this subject. The remarks I am about to make, refer, not to the Hindus, but to a single nation of that great Mongolian race, whose several vast empires lie on the outskirts of British Hindustan, and with whom England is gradually, but surely, coming in contact.

If among these nations we have not the same objects of interest which attach to the Hindu race; if the Mongolians have not been, as far as we know, the first cultivators of science and the teachers of antiquity, still this variety of man has its own importance, and its peculiar interest. It is of high antiquity; it has displayed in its wandering and nomadic life very remarkable forms of civilisation; it is gifted with a bold and determined intellect, which has led its hordes more than once from the deserts of Asia, and the wild steppes of Tartary, into the very heart of Europe. And, at the present time, the mass of the Mongolian or Turanian nations are almost alone in the fact, that as yet they have been comparatively unimpressed by the action of European intellect. Everywhere else in Asia, the traces of Eastern thought and manners, the peculiarities of Eastern civilisation, are slowly but surely disappearing before the overwhelming power of the people from northern Europe. Persia is yielding to the gigantic force of Russia; Egypt and India are virtually the appendages of the British crown; and if, in the recent movement upon Burmah, upon China, and upon Borneo, we see the first attacks of the restless and roving Saxon upon these remote nations, still the impression has hitherto been slight and evanescent; the mind of the people has been as yet unaffected, and the peculiarities of thought are still as distinct as the languages which convey them.

In addition to this, the subject is worthy of being now brought forward, with reference to the Burmese, it has, as far as I know, been absolutely untouched. Opportunity has not yet been afforded to the officers of the East India Company to examine perfectly the medical books of the Burmese, as they have done the Shastras of the Hindus; and I believe the few remarks I have now to make will be all that has ever been made known on the subject. I must, however, apologise both for the imperfection of these remarks, and for the desultory manner in which they are arranged. I have been anxious not to weary the Society by dry details, however curious; and I must also confess that my own knowledge of the subject is so exceedingly slight, that, if it were not for its novelty, I should not have presumed to offer it.

Medicine is practised in Burmah by two classes—by priests and by laymen. The priests have naturally become physicians, because, as among all Bhoodhist nations, science is incorporated with religion, and is included in the sacred books. To become a priest, it is necessary to be a philosopher; the complicated Bhoodhism which is professed is founded on a vast and singular system of physics, which would be very interesting, if I could bring it forward on the present occasion.

This system, which, according to Bhoodhist belief, did not arise from the discoveries of man, but which was revealed in all its completeness by the last incarnate Bhood, Gaudama, necessarily comprehends to some extent the science of medicine, modified, however, in some measure, by commentators and expositors, the writings of whom appear to be all of ancient date. The fact of the theory of medical study being thus connected with religion, would have had the effect of throwing the practice of medicine entirely into the hands of the priests, in the same way as in the middle ages it was confined to the monks of Europe, if it had not been for the peculiar constitution of the Bhood-

hist priesthood. To this constitution I must shortly advert. The Bhoodhist priests are singularly like their Roman Catholic brethren; they form an order apart from the laity; they follow no occupation, but are engaged continually in reading the sacred books and in praying; they live in monasteries or *kyomys;* they are vowed to celibacy, and in some places they will not look on the face of a woman; they live upon alms, and will neither till the ground nor cook their own food, for fear of causing death to some living creature; they cannot own any property; they consider all the usual occupations of men as unworthy their regard, and they endeavour to keep their thoughts continually fixed on abstract virtues and on heavenly rewards. There are many curious resemblances between them and the Romish priesthood. They wear a peculiar dress, keep the head shaved, tell their prayers upon beads, perform innumerable penances for faults, and every now and then retire into solitude, and live for months on the scanty fare which the piety of a few enthusiastic devotees may provide for them. They seem to have no ambition, and no desire of propagandism; in fact, their own supremacy and that of their religion is so completely acknowledged, that there is no room for the development of the ordinary passions of man. They do not mix in the affairs of their nation; they give advice only if asked for it; they occasionally cast nativities at the birth of children, or, in moments of national emergency, consult the stars, for they are great astrologers, and prophesy. It might then be conjectured that these extraordinary men, in the world but not of it, elevated, like their houses, which are built round the temples on the hills, above the turmoil of human events, would not be great practisers of an art, which, more than all others, brings man in contact with his fellow man. Moreover, their creed debars them, as was the case also with the Catholic priests, from the practice of many branches of medicine, such as midwifery, the treatment of syphilis, and surgical operations. They practise medicine therefore merely incidentally, and from charitable motives, without view to profit or honour; at the same time, they have a high reputation, and are often consulted in desperate cases.

A class of laymen practising medicine has therefore gradually arisen, and is of considerable importance among the Burmese. Occasionally medicine is combined with some other pursuit; thus the Burmese doctor with whom I was most intimate, and from whom I learnt the greater part of what I know of the subject, was not only a doctor but a schoolmaster. Although the Burmese have not the divisions of caste of the Hindus, the pursuit of medicine seems to be handed down in families, as was the case among the Asclepiadæ in Greece. The doctors are not in any way licensed to practise, but the public seem generally to employ those who have been regularly trained; they are universally the collectors and venders of drugs. A doctor, or *sathamar,* is educated in the following way. At an early age, he is sent to a monastery, or kyomy, and is educated by the priests. This is the practice also among all the richer laymen. When he is supposed to be learned in all the wisdom of the Burmese, he returns home to his father, who is most probably a sathamar, and commences practice.

His course of study is similar to that common, I should suppose, to all primitive nations. While at the monastery, he has learnt a number

of empirical rules respecting diseases and their symptoms. Of anatomy he has no practical knowledge, although he has some traditionary notions, which are generally erroneous; thus he believes that there are three hundred bones, nine hundred muscles, nine hundred veins, etc. Physiology and chemistry are, of course, quite blanks to him. But he knows an immense quantity of drugs, and their usual action upon the body, and he has his formulæ for using them. He has also been carefully taught the differences of constitutions, and the influence of seasons upon them. It is in reality a completely empirical medicine, which looks not to causes, but to effects; not to the philosophical exposition of a disease, but to its prominent symptom and final result. It often appeared to me, that I saw, in the practice of these rude brethren of ours, a faint glimmering of that art which reached its perfection in Hippocrates; an art which arose from a rigid observation and comparison of symptoms, and of the relief afforded by remedies; an art which must always be true for the locality and habits of the place in which it originated, but which becomes false the moment it is transplanted.

But I must hurry on to consider the kind of rules and principles, with which the Burmese doctor will have commenced practice. The best way to describe these will be to give an abstract of a book on medicine, which was given me by my Burmese friend, as containing a short account of his principles. I must mention, however, that the books on medicine are very numerous, and this is merely one of the shortest treatises.

I cannot pretend to anything like a correct translation; all the medical books are written in the language in which the sacred books are written, viz., the Pali, a variety of Sanscrit; but, in the case of medical books, the Pali is written in the peculiar round Burmese character (which you will see in the book I have sent round, a common book, made of the leaves of the palmyra), and it is also interspersed with Burmese words. In making my translation, I was therefore compelled to get the Pali translated into colloquial Burmese; but although I employed two men, one of them a sathamar, to assist me in translating, we found it impossible in some parts to make sense of it.

The book opens with a preface, containing a long invocation to Gaudama, the last Bhood, praising his power and goodness, and desiring to imitate him. The life of Gaudama, his numerous transformations, and the virtue by means of which he became Bhood, or incarnation of Deity, from man, are detailed at length. Then follows an enumeration of the nine planets, and of the days of the week governed by them. Then the constellations, twenty-seven in number, are enumerated. The days of the week, the planets, and the constellations, are all affirmed to be connected by mysterious ties, and the names of the former are derived from the latter: thus, into *Tanengenwae*, or Sunday, the names of three constellations enter, viz., *Burnē*, *Pubar-burne-gonā*, and *Pu-par-than*, and the same with the other days. However, it is unnecessary to go into these details.

After this preface, there comes a long description of the different temperaments or dispositions of people. The Pali word which I have translated temperaments, was translated into colloquial Burmese by a word *(dar-dath)* which corresponds exactly with the English word "temper".

There are said to be five temperaments; they exist in different proportions in all bodies, but they vary in their proportions in different persons and seasons. They are not described as being attended with any peculiar physical appearance, but it is curious that one of them is said to be attended by excess of bile, and another by excess of phlegm, and another is said, when in excess, to lead to madness. In these, perhaps, we may see the rudiments of the biliary or choleric, phlegmatic, and nervous temperaments, which have descended to us from the ancients, who were, in all probability, long posterior, in point of date, to the authors of the writings I am discussing.

Excess or deficiency in the temperaments produce disease; and these variations arise either from external conditions, as changes of season, etc., or from the agency of demons and evil spirtis. Thus the disturbance of the first temperament (*Ta-so-dah*) produces fever; hence a man has chills and horripilations; he is languid and afraid; has a distaste for food, etc.

The disturbance of the second temperament (*Wy-o-dah*) produces diseases of the chest or the head. If of the chest, there is sneezing, coughing, vomiting, dimness of sight, deafness, languor, restlessness, pains in the limbs, thick sputa. Occasionally there are swellings in the feet, and smarting of the eyes. If the head be more affected, there is pain, or, on the contrary, partial insensibility of the skin; half the body may become insensible; the face is drawn to one side; the tongue is stiff and numb; the fingers are stiff; the hands and feet are crooked; the loins bent.

If *Ar-bo-dah*, the third temperament, be diseased, the skin is affected; hence result venereal cutaneous diseases. The skin becomes copper-coloured, or like red flesh, or of a pale red colour, or like wax; there are spots on the skin and itching; the flesh cracks. Great derangement of this temperament produces small-pox, chicken-pox, and leprosy.

The fourth temperament, or *Put-ta-wye-dah*, produces bowel complaints, diarrhœa, and swelling of the abdomen.

The fifth temperament, (*Ar-can-dhar-dah*), when increased, produces peculiar dryness and scaliness of the skin. At other times, when decreased, it produces great sweating and emaciation; the perspiration is turbid.

The five temperaments are not all equally affected. Before the age of sixteen, phlegm is said to predominate; from sixteen to thirty-two bile predominates; afterwards again phlegm.

Then follows an account of the manner in which these temperaments, or elements of the body, as we might term them, are influenced by seasons. Thus *Ta-so-dah*, whose disturbance gives rise to fevers, is said to prevail in April, August, and December. *Ar-bo-dah* is said to prevail in October and July, etc.; but I need not occupy time with these details.

The next part enters into the description of remedies, arranged under the heads of the temperaments. The formulæ are almost innumerable, and consist chiefly of vegetables; arsenic, mercury, and antimony, are the only minerals named. When the temperament is disturbed, which gives rise to fever, emetics are ordered, and afterwards

spices, cloves, ginger, and numerous vegetables, chiefly aromatic stimulants, and a good many derived from large flowering vines.

But I can perhaps give a better account of their practice, by detailing the method of treatment of certain diseases.

I must first mention, that the diseases of these people are, in some respects, different from ours. Bowel complaints, marsh fevers, rheumatism, small-pox, syphilitic diseases, and leprosy are very common. Beriberi is seen sometimes; bronchitis and pneumonia are met with occasionally; phthisis also, but of its relative frequency I have no idea. Many of the diseases which result from our system of civilisation, from our large cities, the luxury of the upper orders, and the deprivations of the lower, are unknown there. Insanity and nervous complaints are not usual; dyspepsia and kidney diseases seem comparatively uncommon. But, of course, on all these points I speak almost at random; there being, in reality, no accurate data to go upon.

To combat these diseases they use an immense quantity of medicines, of many of which I know nothing. Among those best known to Europeans I may enumerate, opium, hemp, catechu, kino, gamboge, camphor, àreca, cardamoms, and all kinds of spices; anise, chalk, antimony, arsenic, mercury, castor oil, tobacco. Their formulæ are very complex; sometimes as many as sixty substances enter into one preparation. They give chiefly pills and decoctions. One remarkable medicine I must not forget to mention, viz., the "Tabasheer", or inspissated juice of the bamboo; it contains a large quantity of silica.

It is a curious circumstance, that among the sathamars a split or difference has of late years taken place; one class giving medicines in enormous quantity, the other limiting the quantity of medicine, and trusting chiefly to dietetics. In the following account I shall endeavour to describe the practice of the most rational among these two parties.

The most common class of diseases, after fevers, are probably bowel complaints. The food of the Burmese consists chiefly of fish, rice of different kinds, milk, and of various vegetables, particularly capsicum, and spices. They eat no meat, because they will not kill the domestic animals, although they will eat them when killed. In order to correct the acidity of their food, they are accustomed to take, once or twice in the course of the day, a small quantity of chalk and catechu. A few grains of chalk, carefully prepared and coloured with cochineal, are wrapped up in the leaf of a trailing plant belonging to the family of piperaceæ. A little bit of beetel nut is put into the mouth at the same time; and, after the whole mass has been sufficiently chewed, the teeth are rubbed with a tobacco leaf. Their diet almost requires the use of a dietetic antacid and astringent of this kind; it is a necessary luxury, which the poorest Burman indulges in.

When dysentery has once commenced, they endeavour to restrain it by the most powerful astringents, and their practice is very successful. Treat an Englishman in this way and he would be killed; the diarrhœa would not be restrained, or rather it would be aggravated by astringents; but, in the case of the Burman, one has to deal with a different system, and consequently with a modified disease. Dysentery is still inflammatory among them; but it is inflammation of a more passive

kind, running a course somewhat similar, giving rise to the same products, and yet not obedient to the same remedies.

Small-pox is treated admirably. The stages of the disease are well known, and the course of the disease determined. Low diet, the freest ventilation, and cold water, with perhaps a little antimony, form the only measures. The skin is sometimes bathed freely with cold water throughout the whole course of the disease, and this is said to be very useful.

Rheumatism assumes chiefly the form of chronic migratory pains. It is exceedingly common. Rheumatic fever is not, I think, known there. I never heard of it among the Burmese, and I never saw a case among the European soldiers, who would have been, I should think, subject to it. The chronic pains are chiefly treated by baths, shampooing,[1] and counter-irritation, particularly with the juice of certain euphorbia, which blister the skin in a very short time.

Syphilis is a most severe disease, and is, I think, aggravated by the method of treatment. Salivation is produced by fumigation with the fumes of heated mercury, and is kept up for some time. Secondary symptoms are notoriously frequent, particularly phagedenic ulcers of the skin. Accompanying these is a peculiar cachectic state of the constitution, which, when it has once originated, is seldom cured. The Burmans say, that a man so affected is ever afterwards unfit for labour. I may mention, that these unhealthy ulcers were found by a friend of mine, Dr. Tait, who was in charge of the corps of Rifles raised among the Burmese, to be cured very readily by large doses of cantharides.

Bleeding is seldom or never practised in any disease, and leeching is not much used. In fact, depleting measures are obviously unnecessary; the peculiar habit of body would not indicate them, and the severe inflammatory diseases—pneumonia and acute rheumatism—of our colder climate, are unknown there.

The Burmese are subject to some peculiar diseases, for which they have very efficacious remedies. At certain times of the year, chiefly in the rains, they are exceedingly infested with worms, particularly lumbrici. In children, and sometimes in adults, the general health seems completely to fail from the myriads of these animals. The worms are not developed by the peculiar diet of the Burmese, they originate in some peculiarity of climate; this is proved by the English soldiers being equally affected. When my regiment was first quartered in Burmah, we were astonished, at a particular time of the year, to meet with a number of children, who became enfeebled and cachectic, and, without visible disease, wasted and died. At the same time, we were surprised at being spoken to by many soldiers respecting lumbrici, which they said they had vomited. At first I thought little of this, as lumbrici are often vomited even in this country; but, after a time, the number of complainants became so great, that it was impossible not to see there was something more than usual in the case. On inquiry I found that such a disease was well known among the Burmans, who were accustomed to treat it by a certain remedy. This remedy, which they call "Wah-mo, or Wah-than-mo", is a fungus growing upon

[1] They shampoo exceedingly well—better than any other nation, except the Chinese—with elbows, fists, and feet.

the small prickly female bamboo. The Burmese collect it with great care during the rains, and preserve it in a dry place, well covered up. It is always in great request among them, and, in times of scarcity, has been sold for its weight in silver. I did not at first use the *Wah-mo;* but, after trying ordinary purgatives, turpentine, etc., without good results, I commenced with the Burmese specific, and was astonished at its effect. It was soon made out, that the cachectic state among the children was attributable to this immense collection of worms, and a few doses of the *Wah-mo* did wonders. I have known a child, of a few months old, discharge as many as sixty worms at one stool after two or three doses, and in the course of a few hours as many more; and from that time to regain appetite and flesh. It was equally efficacious in men, and the following year the soldiers bought it themselves in the bazaar, and took it in immense quantities. The *wah-mo* has a slightly acid reaction when fresh, and when it loses this, which it does very rapidly, it seems to become inert.

Diseases of the skin are common, particularly different forms of herpes, which seems to take the place which eczema occupies in this country. They use various irritating applications, particularly the acrid juices of some kinds of acacia and mimosa. Sandal-wood, rubbed down into a paste with water, is used for this purpose, and also by women as a cosmetic.

Leprosy is a very common disease, and is considered hereditary; so that the children of a leper, although not themselves leprous, are allowed to intermarry only with the children of other lepers. Lepers immediately become outcasts; and, in Burmah Proper, are obliged to live in leper villages, and to wear a peculiar dress. Although there is this rule, there does not seem to be any feeling of disgust entertained against this class, and wives will often follow their leprous husbands into retirement, and continue to cohabit with them. The government of these villages, in Burmah Proper, is a place of great emolument; as there is a great power of extorting money from persons who have any cutaneous disease, on the plea of their leprosy. Leprosy is considered incurable by medicine.

Hydrophobia appears to be known, although I never met with any one who could describe it. In the oath, administered in their solemn courts of justice, the Burman has to say, among other things, "If I speak not truth, let me be subject to all the calamities that are within the body, and all that are without the body; may I be seized with madness, blindness, deafness, leprosy, and hydrophobia; may I be struck with thunderbolts and lightning, and come to sudden death; may I vomit clotted black blood, and suddenly die in the midst of the people."

I am afraid of becoming tedious by going into further detail on these points. It will be perceived that the practice of medicine is empirically good, in so far as symptoms are combated by medicines whose use has been established by experience. The theory to explain the diseases, and the action of remedies, is utterly worthless, and has possibly been framed to accord with the practice, and not from any induction from phenomena.

I will now offer a few remarks upon the practice of surgery and midwifery among the Burmese.

Operative Surgery is almost unknown; and this is the more surprising, as malignant tumours are, I think, rather common, and must have been recognised as highly dangerous. But the Burmese have a great repugnance to use the knife. Abscesses they almost always allow to burst; and they foment them assiduously, in order to bring them quickly forward. I operated a few times among them, but performed only the minor operations, and these were almost always done in opposition to the advice of the sathamars.

Fractures they treat tolerably well with bandages, and means to keep the limb in position. I believe, also, they know how to reduce dislocations, but I never saw them do it.

Their Midwifery is, perhaps, the worst point about their practice; and there is great mortality, both among mothers and children. Labour is allowed to go on undisturbed till the child is born. The placenta is then forcibly detached, and an immense stone is placed immediately over the uterus, to hinder the copious flooding which often occurs. As soon as the bleeding has stopped in some measure, a large ring of fire is kindled round the bed, and kept up for nearly twenty-four hours. The child is not put to the breast, and the unfortunate mother, intensely hot, perspiring at every pore, and with a tremendous pulse, is hardly allowed to drink anything besides hot spicy infusions. I have been allowed to visit women after this tremendous ordeal, and have found them sometimes completely debilitated and exhausted; sometimes in a high state of fever. Many women, in fact, die, but from what form of puerperal or milk fever I could never learn.

It is not, perhaps, fair to charge upon medicine this extraordinary penance which the newly-delivered woman is obliged to pass through; it is, in fact, a religious ceremony, and the ring of fire is intended to scare away the evil spirits, of whom there are multitudes in Burmese mythology, and who would soon injure the woman, and through her the child, if they were able to pass the fiery belt drawn round her.

I have not alluded at all to the practice of charms, although this is very common; not, however, so much among the doctors as among the other laity. All epidemic diseases, such as cholera, small-pox, etc., are referred to the malice of demons, who are propitiated by gifts, invocations, and various curious charms. There is a very singular superstition connected with cholera. This disease is believed to be altogether a punishment for crimes. When the patient dies, his soul is released, and over that the evil spirit has no power; he can, however, seize the dead body, and wreak some mystical indignities upon it. To prevent this, directly the last respiration has been drawn, the friends of the deceased assemble round the corpse, and, with wild gestures, shout out certain sentences which are supposed to scare away the demon hovering over. These shouts are continued until the body has been carried to the place where such ceremonies are performed, and has been burnt. When all traces of humanity have been consumed by the flames, the disappointed demon is supposed to retire discomfited from the field.

I feel that I have already been too prolix on these details. I will occupy the Society only a minute longer, while I allude to the practice of Opium Smoking among the Burmese. Among all the Eastern

nations this practice prevails; and it is curious enough that the name is nearly similar in all nations, however different their origin and manners. Among the Burmese and Malays the name is "afyun", which is the same nearly as the Arabic word "afioon", and the Hindoo "aphion". I have been informed that the Malay term is the original one. Dr. Royle, however, a great authority, thinks they all come from the Greek *οπος*, juice.

Among the Burmese, opium smoking is a luxury; and the rich indulge in it a good deal. They smoke in the same way as the Chinese. The finest opium is made into a watery solution, then slowly evaporated, and the resulting extract rolled into little pills. Each pill is placed in a hole at the side of a pipe, is lighted by the flame of a little silver lamp fed with naphtha, and suffices for three or four inhalations. After several of the grains have been used, the Burman has had enough; it has merely made him lively and active. It has in no wise made him sleepy. This is a curious effect; and it is worthy of remark, if it be always the case, how differently this same drug affects different nations. From a moderate dose, the Chinaman becomes tipsy, or falls into a reverie; the Malay is rendered furious and excited; the Burman is merely slightly roused. It is a common thing, when a Burman has any difficult work to do, for him to take a pipe or two of opium; he then works for six or eight hours with unusual energy and skill, and afterwards falls into a sound and refreshing sleep. In large doses, the effect of opium is the same on people of all nations. They pass first into dreamy reveries, and then into deep sleep, or coma. The Burmese describe these reveries as foretastes of heaven, or what in their mythology corresponds to heaven, *naik-ban*. Opium is too dear to be very much used, and consequently I have never seen among the Burmese the debilitating effects which are said to occur among the Chinese. But, both among the Burmese and the natives of the Malabar Coast, the chewing and smoking hemp has appeared to me more hurtful than opium.

I think that it may be concluded, even from the few observations I have ventured to bring forward, that, although theoretically the science of medicine is at an exceedingly low ebb among the Burmese, yet its practice is not so destitute of a certain degree of reasonableness as we might have supposed. In fact, I have no doubt that much good is really done by the practitioners of medicine; and I am the more confirmed in this opinion, because their treatment is very much trusted to by their countrymen; and I believe when a whole nation has faith in a particular method of treatment, one may feel pretty certain that this method is, to a certain extent, capable of a successful application. Thus, however erroneous may be their pathology, I have some faith in the Pharmacopœia of the Burmese physicians; and I cannot deny them the credit we claim for ourselves, viz., that of being helpers of men, and useful in our day and generation.

13, Harley Street, Cavendish Square, April 1851.

ON THE SYMPTOMS, DIAGNOSIS, AND TREATMENT OF THE FUNCTIONAL DISEASES OF THE UTERUS.

By T. SNOW BECK, M.D.Lond., Fellow of the Royal College of Surgeons; Physician to the Farringdon General Dispensary and Lying-in Charity; Secretary to the London Medical Society of Observation.

(Read before the Medical Society of London, March 29, 1851.)

When I decided to draw the attention of the members of this Society to the Functional Diseases of the Uterus, I soon became convinced that only a fraction of the questions which this subject naturally gives rise to could be considered, during the short space of time which is allotted to the reading of a paper; and hence arose a fresh difficulty, viz., the selection of the points most worthy of consideration. After some thought, I have come to the conclusion, that the most practical method of treating the subject will be to take a case which has occurred in practice, to detail the history, symptoms, and treatment, and then to consider what conclusions can be drawn from the facts thus brought forward.

Case. The case is that of a young lady, E. W., aged 26, spinster, who came under my care on October 29, 1850, when she gave the following history of herself.

The catamenia appeared at about sixteen years of age, and were accompanied with much pain at the lower part of the stomach and across the forehead; previous to this time she had "nothing the matter". The catamenia were now absent for twelve months, during which period the health was very delicate. She described herself as looking "very bad", being thin, very languid, and generally obliged to lie down every afternoon; as having a cough, no appetite, pain in the left hypochondrium, and much aching pain in the lumbar region and inside of the thighs. These last symptoms returned every fortnight or three weeks, and continued a day or two; she then "used to be pretty well", but the headache remained every day, more or less. For some months she was under the care of a surgeon, but experienced no relief from the medicines, which, she thinks, were various preparations of steel. Three months after the medicines were discontinued, the catamenia appeared for the second time, and were accompanied with great pain for two or three days. They were of a dark colour, continued nearly a week, and were not followed by any white discharge.

From this time the health was totally changed; she became stout, had much colour, and the spirits were very good. The catamenia appeared every month, within a day or two, accompanied with some headache and slight pain in the lumbar region and inside of the thighs. They were generally of a dark colour, and remained about five days; the quantity was not great, and they were usually followed by a white discharge for one week afterwards. The accompanying pains came on a few hours before the menstrual discharge, and remained for a day or two, gradually becoming less.

For four years she continued in this state of health, running about and dancing a great deal, whether the catamenia were present or not.

She was now attacked with what was termed "bilious fever", which was so severe, that her friends had no hopes of her recovery. It came on with flushes in the face, and great pain in the head; afterwards she was very thirsty, and drank much cold water; she was also very sick, vomiting large quantities of sour fluid, about half a pint three or four times a day, when, after a good deal of straining, a little yellow matter would come up. Great pain was also present in the back, the lower part of the stomach, and all over the thighs, but chiefly in the front and inside. These situations were also very sore if anything touched them, and had the feeling of being bruised or beaten. For three weeks she was unable to leave her bed; and during great part of this time she was delirious. When partly recovered, she left home for change of air, and gradually got about again—that is to say, she got much better. The appetite was very good (she always, indeed, felt hungry, with a sinking and craving at the epigastrium); she gained some flesh, but was never so stout as before; and she always felt wearied and languid, being soon worn out by any slight exertion, and was more subject to headache than before. The catamenia continued regular in recurrence; the accompanying pain about the same; the quantity diminished; the colour became lighter; and the white discharge increased in quantity and in duration.

During more than three years she remained in this, as she considered, delicate state of health, when, eighteen months ago, she was again confined to her bed for three weeks. This illness began, during the catamenial period, by the face being much swollen, and of a dark purplish red; and was attended with cold shiverings, and much fever. As in the former illness, she again had great pain in the lumbar region, at the lower part of the stomach, round the hips, and all down the inside of the thighs. The bowels were not moved for a fortnight, although she took a great quantity of castor oil. She felt very sick, but did not retch much. The medical attendant described the attack as "partly erysipelas", and ordered warm fomentations for the pain in the stomach, which gave some relief. She stated to me that the medicines "did not do any good", but that she gradually got about again, when she felt very weak, the spirits being extremely low. The stomach was so tender that she could not stand upright, but was obliged to walk double; her friends jocularly remarking that "she looked like an old woman after her confinement". It was now told her, that her illness was caused by not taking sufficient exercise; and she was ordered to get out of doors, and to keep the bowels open, for which she had some pills which griped very much. Her health was worse than it had previously been. At one time, however, it so much improved, that she thought it was going to be completely restored, when all the old symptoms returned, and she was just as she had been. After suffering in this way for nearly eighteen months she came to London, and presented the following symptoms.

She was rather tall and thin, with dark hair, dark eyes, swarthy complexion, and medium conformation. The expression was dull, heavy, and depressed; the lips of good colour; but the upper lip was much swollen, and of a dusky red. She felt very weak, faint, and inclined to be hysterical; had lost much flesh lately, particularly in the bosom, and about the upper part of the chest. On the day before I

saw her, she could only sit up for one hour and a half. The least exertion caused fatigue, when drops of cold perspiration would stand on the face, a singing noise be induced in the head, and attended by a great sensation of palpitation; she also had frequent feelings of faintness and sinking during the day. A dull pain was complained of across the forehead, attended with a feeling of tightness, and occasionally a hot heavy pain at the top of the head, at which time the face "feels so hot". The head very often, but not always, felt full, and frequently was much confused. The spirits were very low; she was easily excited, and started much at any noise. She felt rather nervous and irritable, which she tried to overcome; and sometimes she had the feeling as if something dreadful were going to happen to her, which was relieved "if she could cry". The memory was very bad, and much indecision had come on, which was not the natural character. Sometimes she slept pretty well, but had very bad dreams; sometimes she "could not sleep at all". When she did sleep, she frequently awoke with a start, frightened and perspiring. The eyes felt heavy and aching; the eyesight was dull and impaired. The skin was soft and cool, with some moisture. She always felt chilly, though the face and hands were subject to frequent hot flushes; nor could she bear either heat or cold. The pulse was 108, regular, rather small, and soft; no venous murmurs were heard. The tongue was rather large, pitted at the edges, which, as well as the under surface, were of a red colour; the centre being covered with a dirty white fur. She had a very unpleasant bitter and sour taste in the mouth, much thirst, and no appetite. She had not taken meat for the last month. Sometimes a sinking at the chest was felt, as if she wanted something, yet could not eat. There was no pain nor distension after taking food; but the stomach sometimes swelled very much, chiefly in the evening, before going to bed. The bowels were at the time confined; sometimes they were regular. The urine was pale, and in considerable quantity; at other times it was darker, less in quantity, thick, and deposited a red sediment on standing. Much complaint was made of a constant pain in the lumbar region, shooting up as high as the middle of the dorsal region. From the lumbar region it extended round the hips, and was most severe in the iliac regions, extending from thence to the hypogastrium, the groins, and the anterior part and inside of the thighs, which latter parts were very sore. The pain did not extend below the knees. From the upper lumbar region, pain also extended round the upper part of the abdomen, below the epigastrium. "A distinct pain" also existed in the sacral region, and extended round the glutæi muscles, and down the outside of the thighs, as far as the knees. The pain in the sacral region produced a feeling as if the back was broken, or as if she "wanted something to bind it up". For two days lately she had been lame in one leg, and could not walk across the room; she described this as not having power over the leg to stand, and feeling that the inability came from, or was connected with, the sacral pain. It came suddenly, and went away suddenly, in the night during sleep. She was always obliged to be very careful on sitting down, as this hurt her, giving the feeling of sitting upon some tender body. When the bowels were moved, great pain was felt, as if the motion passed over a tender substance deep in the pelvis, whilst a distinct pain was

felt at the anus. The pains extended up the back, and round the lower part of the stomach, and were not always equally severe. The catamenia were irregular in recurrence (six or seven weeks, and sometimes three months), and were accompanied by a great aggravation of all the pains described; they continued not more than two days, were very pale, and were followed by a great quantity of yellow discharge, which was constantly present.

On local examination, the vagina was found narrowed by the strong contraction of the muscles of the perinæum. It was hot, tender, swollen, and velvety to the feel; whilst the arteries, along its walls, were felt to pulsate strong and full. Passing the finger up to the uterus, this organ was found to be low, and somewhat behind the perineal muscles. It was very tender to pressure, hot, and swollen, having a somewhat soft and distended feel. The lips were smooth, with a well marked velvety surface, the orifice nearly natural, the neck enlarged, and surrounded by mucous membrane lying in circular folds; whilst the pulsation of the arteries was strong and quick. As no impediment was offered, by the existence of a marked hymen, to the introduction of a small speculum, this instrument was passed up to the uterus, when the lips were found somewhat enlarged, perfectly smooth, of a dusky brick red, and without a trace of abrasion or of ulceration. The mucous membrane of the vagina was of a similar, but deeper, dusky brick red colour. Some purulent matter entered the instrument.

Six leeches were applied to the anterior part of the uterus, and directions were left to encourage the bleeding to about half a pint. A saline diaphoretic mixture was directed to be taken three times a day, the warm hip-bath to be used for a quarter of an hour each night, and perfect rest to be maintained.

Nov. 1. The leech-bites had bled freely, and caused a faint weak feeling, but the pains were very much relieved, and more benefit had been experienced than from any means yet employed. Pulse 100, regular, and soft. The head felt rather light, but clearer. She was less nervous, and felt better. She was desired to continue the remedies.

Nov. 8. She continued improving; the vagina was much less tender, not so hot, and the arteries beat with less force and quickness. The surface was lubricated with a fluid, which was oily-like to the finger. The uterus was less tender and swollen, and the arteries beat with diminished force. In walking from the bed to the fire she staggered, yet expressed herself as being much better. The leeches were again applied; a pill, containing two grains each of blue pill and extract of henbane, was ordered to be taken each night, and a lotion of decoction of poppies and acetate of lead to be used twice a day.

Nov. 15. Reported herself as much better in every respect. The pains were all lessened; the discharge, though still yellow, was not so great. She slept better, though still annoyed by very unpleasant dreams; the appetite was much the same, the general strength much improved, so that she could now walk about with considerable ease.

Nov. 26. She had had an increase of the pain, in consequence of exerting herself more than usual, in order to assist in nursing her sister's children, who had been attacked with typhoid fever. The local tenderness and swelling of the vagina continued to diminish, as did also the force in the pulsation of the arteries. The uterus was still

rather tender, slightly enlarged, and rather firm to the feel; but the pulsation of the arteries was only perceptible on the left side, where they beat quickly, but were small in volume. Pressure upon this part increased the pain in the left iliac region, and in the stomach and lumbar region. The leeches were again applied, and rest enjoined; and she was directed to continue the other remedies.

Dec. 3. The catamenia appeared yesterday, the accompanying pain being nothing to what it had been. They were high coloured, and yet not inclined to black: the quantity not great In every other respect, she was very much improved. The leeches were repeated the day after the cessation of the catamenia, and the other remedies were continued.

Jan. 3. The catamenia appeared two days ago, with so little inconvenience, that it might be said she had no pain; she considerd herself quite well, and was most anxious to return to the country. She had gained flesh, slept soundly and well; the spirits and appetite were good; the bowels rather confined, the memory much improved, the head clear. At her earnest solicitation, she was allowed to return home, with strict injunctions to continue the warm hip baths, once or twice a week for a time; to rest a little each afternoon, and to take a saline bitter tonic twice a day.

Feb. 28. I received a communication from her, in which she said that she considered her health perfectly restored, and had gradually ceased to use the bath and the medicine.

Remarks. On glancing over the previous history of this case, it is evident that, at the age of sixteen, the patient having been previously in good health, an unusual degree of congestion of the uterus accompanied the commencement of the menstrual function. After the disappearance of the catamenia, the accompanying congestion remained, as was shown by the languor, want of appetite, pain at the hypochondrium, and the aching pain in the lumbar region, and inside of the thighs; and this affected the general health. A surgeon, misled, we may suppose, by that delusive system of considering a symptom of a disease as the disease itself, considered the disorder to be amenorrhœa attended with debility, and administered steel remedies, in order to procure the regular recurrence of the catamenia. This was not successful; nor is it likely that it should be, for, although iron is eminently efficient in removing that state of the blood upon which anæmia and chlorosis depends, it is most injurious when administered during congestion or chronic inflammation of the uterus, acting as it does, as a direct stimulant of the uterine organs, and hence perpetuating these morbid states. Did it in this case produce such an effect? Although I am not in a position to give a decided answer to this question, yet the probability is that it did; and that, when the actions of nature were no longer interfered with, they, to a certain extent, recovered their healthy condition. Three months after the remedies were discontinued, the catamenia appeared for the second time; though the uterus was still labouring under an undue congestion; as evinced by the great pain which accompanied menstruation, and by the dark colour of the discharge; and there was now also congestion of the vagina, as shown by the white mucous discharge.

From this period the health greatly improved, and for four years continued good; yet the original congestion of the uterine organs re-

mained, as is proved by the pains which attended menstruation, the dark colour of the blood, and the subsequent white discharge. She was now attacked with what was called "bilious fever", but which was, really, inflammation of the uterus. The symptoms which prove this were: great pain in the lumbar region, at the lower part of the stomach, and the front and inside of the thighs, delirium, great pain in the head, and sickness, attended with much straining, and vomiting of large quantities of sour fluid. How far this attack was to be attributed to the imprudent course of running about and dancing, which she was permitted to follow, I will not stop to inquire, but will only say that probably this was the cause. From this attack she partially recovered, with the uterine congestion more marked than before, and the general health in a shattered condition.

For three subsequent years the health remained in this state, when she suffered from another attack of inflammation of the uterus, of less severity than the former. This is shown by the cold shivering and the fever; the pains in the lumbar region, lower part of the stomach, and inside of the thighs; and the constipation of the bowels. No relief appears to have been obtained from the remedies employed; but she again got about, bearing the evident marks of serious uterine disturbance—great general weakness, depression of spirits, and inability to stand upright in consequence of the tenderness of the stomach, and the general appearance, which caused the jocular remark of her friends, "that she looked like an old woman after her confinement".

Symptoms. The symptoms, of uterine disease, such as were presented by my patient when she came under observation, may for convenience be divided into groups—direct, constitutional, and local.

In the group of *direct symptoms*, or those which arose directly from the disease itself, we may place, the pains in various parts of the body, the condition of the menstrual function, and the vaginal discharge.

The pains which were present in this case, were pains in the lumbar region, shooting up to the lower dorsal, and extending round the hips, across the sides of the abdomen, towards and into the hypogastric region, the groins, the anterior and inside of the thighs; also extending from the upper lumbar region round the upper part of the abdomen. At the same time, to use the patient's own words, "a distinct pain", giving the feeling as if the back "wanted something to bind it up", existed in the sacral region, extending round the glutei muscles, and down the outside of the thighs as far as the knees. Can any answer be given to the question—Why are the pains found in these situations? Will the anatomy of the nervous system of the uterus afford any clue to the explanation?

It has been pointed out that the portion of the nervous system, called the sympathetic, consists in reality of an admixture of the true sympathetic—the gelatinous fibre,—and of branches of spinal nerves—the tubular fibre;—and that by this means the various viscera have distributed to them branches from the cerebro-spinal system. It has also been shewn that, in addition to the nerves coming from the lumbar plexus, and distributed to the muscles and skin of the lumbar region, the muscles and skin of the abdomen, and the muscles and skin of the anterior and inner part of the thighs, nerves, likewise de-

rived from this plexus, are distributed to the lower portion of the uterus, through the medium of the hypogastric plexus. The organ is thus placed in direct relation with the nerves coming from the lumbar plexus, by means of the branches of spinal nerves, which are derived from the same plexus, and distributed to this organ. Now, bearing these facts in mind, and remembering that alterations of sensation may be reflected through the spinal cord, in the same manner as motor actions, we have a beautiful and scientific explanation why, in this case, in which the uterus is affected, the pains are felt in the parts supplied by the nerves derived from the lumbar plexus,—to wit, in the lumbar region, the sides of the abdomen, and the thighs. This, however, explains but a portion of the pains which were present. Another distinct class were seated in the sacral region, and extending from thence to the posterior part of the thighs. How are these to be accounted for? If we again turn to the anatomy, we find that the nerves which supply the vagina are not derived from the lumbar plexus, but come from the sacral plexus, which likewise supplies the skin and muscles of the sacral region, of the hips, of the perinæum, and of the posterior part of the thighs. Again, bearing these facts in mind, and remembering that sensory impressions derived from the vagina are reflected along the nerves derived from the same plexus as furnishes the vaginal nerves, we have an equally satisfactory explanation why, in the inflammation of the vagina, here present, the pains should be seated in the situations in which they were found.

As the consideration of these hitherto inexplicable pains is of great importance, as a means by which uterine affections may be distinguished from other diseases, and also as a means of diagnosing, whether the uterine affection be seated in the vagina, or in the uterus, or in both organs combined, or in the ovary, I may be allowed to make a short digression from the strict consideration of the case before us. It has been stated, that when the vagina is affected, the pains are reflected along the course of the nerves derived from the sacral plexus, and that when the lower part of the uterus is the seat of the disease, the pains are felt in the parts supplied by nerves from the lumbar plexus; both which statements are illustrated by the present case. But suppose the body of the uterus be the seat of the disease, where then are we to look for the pains which will be induced? Let us again turn to the anatomy, and see what that teaches. It informs us that the spinal nerves, which are distributed to the upper part of the uterus, are supplied by the intercostal nerves, branches from which pass inwards over the thoracic sympathetic, and join together to form the splanchnic nerves; and that the fibres which compose the splanchnic nerves traverse the semilunar ganglia, and contribute to the formation of the superior aortic plexus, from which the upper part of the uterus is supplied by nerves. From these data, we would expect, when the body of the uterus is the seat of disease, that the reflected pains would be found along the course of the intercostal nerves. And such is the fact. Did time permit, I could submit different clinical observations in support of this *à priori* conclusion; wherein most severe and obstinate pains, traversing the course of the intercostal nerves, and chiefly seated over one or both hypochondria, were found to depend upon inflammation of the fundus uteri, and

were immediately relieved by the application of a few leeches to the upper part of the neck of the uterus, that being the nearest available point to the seat of the disease.

It must not be supposed, that in every case the pains will be reflected along all the nerves which are in relation with the organ which is affected. In severe cases, such is the fact; but in less marked cases, one or two only of the nerves may be affected, or the pain may be chiefly confined to the terminal branches of distribution, producing an ill defined pain over a particular region of the body. Yet at all times, the principles which have been stated will materially facilitate the just appreciation, if they do not afford the means of an absolute diagnosis, of a large proportion of pains which are well known to accompany uterine disease, but of which no explanation has yet been given.

To return now to the present subject. Although the menstrual function and the vaginal discharge are in many cases, as in this, important signs of the condition of the uterine organs, yet nothing, it appears to me, has tended more to retard the scientific advance of uterine pathology than retaining, even to the present day, the artificial division of uterine affections, founded on the alterations of these functions. This is the more to be regretted, as the menstrual function is in no wise an indication of the nature of the disease which exists. In this case it was established at sixteen, and subsequently suppressed for twelve months, then to be re-established with regularity. And although the health was said, at this time, to be very good, yet, had attention been paid to the accompanying pain, the dark colour of the flow, and the subsequent white vaginal discharge, it would have been evident that a degree of congestion remained, which required but some want of attention to fan it into an attack of inflammation—a state of things which actually occurred. After this attack, the menstrual function, though regular in recurrence, still indicated that the original congestion remained;—but it indicated more: for it gave evidence, by the lighter colour of the flow, that the general health was suffering. At a later period, the great aggravation of the accompanying pain, and the continuous yellow discharge, were indices of inflammatory action in the uterus and vagina; whilst the irregularity of the recurrence of the catamenia, the diminished period of their flow, and the very pale colour they assumed, too clearly indicated the great influence which the continued suffering had produced upon the general health. It is worthy of remark, that the mucous and purulent discharges which accompany these cases are formed by the vagina, and do not in any way indicate the condition of the uterus, which may be seriously affected without any vaginal implication, and hence without any accompanying discharge.

The *constitutional symptoms* indicate that the digestive system, the nervous system, and the general health are affected; but they likewise show a great immunity of the respiratory and circulating systems. The disorder of the digestive system is marked by the œdematous and furred tongue, the disagreeable taste in the mouth, the want of appetite, the sinking at the epigastrium, the distension of the stomach in the evening, and the alternating condition of the bowels and urine. But these conditions do not indicate so marked a derangement of this system, as appears necessary to produce the disorder of the nervous

system and general health which is likewise present, and hence cannot be considered as the cause of the illness, but must be looked upon as one of the consequences of some other cause, which produces in like manner the disturbance in the other systems. An attempt has been made to connect the alternating conditions of the urinary secretion with a mal-assimilation of the food, and hence to use this secretion as a sign of the treatment required. In this, however, I cannot agree. The regular action of the kidneys is apparently disturbed by the same cause which disturbs or disorders the other organs of digestion. This is shown by the state of the urine varying in the same ratio as the original disease varies. When the pains in other parts of the body become intensified, indicating an aggravation of the uterine disorder, whether this be caused by the congestion which accompanies the catamenia, or from an increase in the disease, the urine becomes deeper coloured, scanty, thick from the deposit of lithates, and requires to be voided more frequently than before. But when the opposite state prevails, and the uterine affection is improved, the urine then becomes abundant, clear, and pale. These alternations are frequently observed during the course of these affections, and take place when the same course of diet has been continued throughout the variations. There can be little doubt that an improper diet, taken while the digestion is already impaired, will increase this disorder; but still this is not the original cause of the disturbance in the urinary functions.

The disorders of the nervous system are by far the most apparent. The various reflex pains which have been already considered, and which continually harass the patient, belong to this class of symptoms. In addition, we have pain across the forehead, and at the top of the head, with fulness, and occasional confusion of ideas; also loss of memory, depression of spirits, increased excitability and irritability of the nervous system, restless nights, harassed by frightful dreams, and impaired eyesight. Another condition of the nervous system, which is only indicated in this case, is one of great interest, and one which I hope to take up at some future opportunity. I allude to the fact of the sudden loss of power over one leg, and the sudden regaining of this power whilst asleep. I have met with some well marked cases of this description, where the patient had been treated for diseased spine, in consequence of the peculiar pain present in the sacral region. In some, a complete paraplegia existed in regard to the motor power, whilst the sensation was not perceptibly altered from that of health; in others, an incomplete hemiplegia existed. In all, the paralysis passed away as the uterine disease, which apparently produced it, was gradually cured, and the health regained its tone.

The evidence of the impairment of the general health is found in the loss of flesh—particularly marked about the chest, and especially at the bosom—and the increased frequency of the pulse. In this case we may also add the general weakness and languor, together with inability for exertion, which, when attempted, was followed by cold perspiration, singing in the ears, and beating of the heart. It does not, however, appear that we can in all cases attribute these latter symptoms to derangement of the general health; for they occur too early in the course of the disease for this explanation to be admitted; and further, the marked manner in which they are often connected

with the appearance of the catamenia, shows that the condition of the uterus, acting on the nervous system, is sufficient to produce them.

In casting a retrospect over the constitutional symptoms present in this case, we find that the nervous system was especially affected, and that this was attended by disorder of the digestive system. How is this to be accounted for? Will the anatomy and physiology, of which so much use has been made, assist in this explanation? I think it will. In addition to the anatomy of the nervous system affording a beautiful explanation of the various pains which accompany uterine disease, it further teaches, that the viscera of the abdomen are supplied by spinal nerves from the same nerves or plexuses which furnish branches to the uterus, *i. e.*, the dorsal and the lumbar nerves. These nerves send branches inwards, which become mingled with the gelatinous fibres of the sympathetic, and are distributed in company with them to the various viscera. With these anatomical facts before us, and with the knowledge that pains are reflected along the nerves supplied from the lumbar and intercostal nerves to the back, to the walls of the chest and abdomen, and to the thighs, we have a fair reason to infer that similar pains will be reflected along the branches furnished from these same nerves and distributed to the viscera.

This inference acquires additional confirmation from the "working" frequently felt in the bowels, and the tenderness of them which is present, independent of the tenderness in the abdominal walls. If this reasoning be correct, we are enabled to give a satisfactory explanation why the abdominal viscera should be disordered, which clinical experience has taught us is the fact. But is this derangement in the condition of the nerves sufficient to account for the derangement in the functions observed? I submit that it is, and that it affords a sufficient reason why the respiratory and circulating systems should be so little implicated. The nerves, which supply these systems, arise from the spinal cord higher up than the origin of the uterine nerves, and hence are not implicated in the series of reflex actions to which these diseases give rise. It is right, however, to call to remembrance that, in the case under review, the pulse was accelerated, and the heart beat strongly on exertion. These symptoms, however, appear to depend on the state of the general health; for it is well known that, as a rule, the pulse is not increased in frequency, nor is there palpitation of the heart, except when some constitutional state is present at the same time.

The *local symptoms* have been already detailed, and do not require further examination. They afford indisputable evidence of the existence of inflammation of the vagina and of the uterus.

From a short review of the pathology to which the examination of this case has led, we have the following propositions:—

1. The symptoms by which uterine disease is recognised are chiefly referable to derangements in the nervous system; which consist of
   (*a*) Pains reflected from the uterus to various parts of the body.
   (*b*) Irritation of the spinal cord, and its prolongation into the brain, communicated to the various organs through the spinal nerves distributed to the uterus.
2. The reflex pains, which have so much puzzled the physiologist

and the pathologist, are beautifully explained by attention to the anatomy of this portion of the nervous system.

3. Next to the nervous system, the organs seated in the abdomen are those which are chiefly implicated in the derangement.

4. The derangement of these abdominal organs may be explained by the irritation of the uterine nerves being reflected through the spinal cord, along the spinal nerves distributed to these organs, which nerves arise from the same part of the spinal cord as the uterine nerves.

5. The respiratory and circulating systems do not suffer from uterine disease, until this disease has existed a sufficient length of time to derange the general nervous system, or the general health.

6. The immunity of these systems may be explained from the fact, that the nerves, which are distributed to them, arise from the spinal cord, or its prolongations, higher up than the uterine nerves, and are, hence, not implicated in the reflex phenomena which exist.

7. The general health finally becomes implicated by the want of appetite, the deranged digestion, the want of sleep, the little which is gained being disturbed by frightful dreams; and by the constant state of irritation and pain which the patient habitually suffers, and which is greatly increased for several days, at each catamenial period.

8. And, as a corollary to these propositions, I may add that, when we remember that the organ under consideration is destined to have a periodic afflux of blood to it, to take on greatly increased arterial action, and to undergo wonderful enlargement as a physiological condition, all apparently designed by nature to occur without implicating the general health of the female;—we have a reasonable explanation why the diseases of this organ should affect the general system so little as they do.

Diagnosis. It is necessary to consider the diagnosis apart from the local symptoms, as it is important to establish it, before submitting the patient to a local examination.

From *Anæmia*. The symptoms which favour the idea of this disease being present are, the general weakness, the languor, and inability to exertion; the latter being followed by perspirations, singing in the ears, and beating of the heart; also the lowness of spirits, the nervous excitability, and the irregularity and pale colour of the catamenia. But the symptoms which contraindicate it are sufficiently well marked; they are the complexion, the red colour of the lips and mucous membrane of the mouth, the character of the pulse, and the absence of venous murmurs, or arterial whiffs: whilst the nervous irritability which is present, the pain in the head, the sleepless nights and frightful dreams, the pains in the back, abdomen, and thighs, the great pain attending the catamenia, and the yellow vaginal discharge, all too clearly point to the uterus as the organ chiefly implicated. I am aware that, in this appreciation of the symptoms, I may differ from some of our most esteemed authors; yet I feel assured that, in the description usually given of anæmia, authors have included symptoms which properly belong to functional diseases of the uterus, in consequence of these two affections being, not unfrequently, met with combined in the same individual. The state of health which is produced by the functional diseases of the uterus, is, however, very distinct from that of anæmia, though frequently confounded with it.

From *Rheumatism*, the diagnosis presents some difficulties. The aspect of the patient, the state of the digestion, the condition of the urine, which is high coloured, and depositing lithates, and the seat of the pains, might mislead. For we must remember, that the pains which accompany uterine diseases are seated in the nerves which supply the muscles of the back, abdomen, and lower extremities, and consequently might readily be mistaken for pains seated in the muscles themselves, especially as they are aggravated by the action of these muscles. But the exact seat of the pains, the course which they pursue, their aggravation during a catamenial period, the varying condition of the uterus, the disturbed state of the nervous system, and the general condition of the patient, aided by the previous history, will suffice for a correct diagnosis. Some authors consider that some functional diseases of the uterus essentially depend upon a rheumatic condition of the system, present at the time; and certainly the relief which is sometimes obtained by rheumatic remedies favours this view; but how far this may be accidental, and not essential, I am not prepared to say.

From *Disorders of the Digestive System*, this case offers little doubt in the diagnosis. The digestion was certainly disordered, but the disorder bore no relation to the general derangement which was present. In some cases which are attended by obstinate constipation of the bowels, with frequent sickness, and great pain in the forehead, as a sequence of this constipation, the diagnosis becomes difficult, especially from the reflected pains from the digestive organs being seated in much the same situation as the reflected pains from the uterus. The reason for this is obvious, on reflecting that the spinal nerves distributed to these organs are derived from the same part of the spinal cord. However, a careful consideration of the history and symptoms will suffice to form a diagnosis.

From *Disease of the Kidneys* there could be little hesitation in forming the diagnosis. The only disease with which the uterine affection was likely to be confounded, was pyelitis; but as this disease is generally confined to one kidney at one time, and as the pain in this case existed equally in both lumbar regions, the chances were greatly against the existence of this affection. However, I have known a similar affection of the uterus mistaken for a pyelitic attack. The circumstances which led to this error were, pain over the region of the kidneys, chiefly confined to one side, and increased on pressure; pain shooting down the side of the abdomen, simulating the course of the ureter; pain in the inside of the thigh; the urine being acid, containing pus-globules, and occasionally being impregnated with blood-discs and albumen. But on a careful examination of the symptoms, these errors were readily detected. The pain was not exactly over the seat of the kidney; it was more superficial, being evidently reached before the pressure could have affected this organ; it was likewise not present on pressing the kidney from the abdomen. The pain in the course of the ureter was also seated in the walls of the abdomen; the mixture of pus-globules with the urine was detected to arise from the purulent vaginal discharge, whilst the occasional presence of blood and albumen was derived from the same source during the presence of the catamenia. By attention to these points, the diagnosis was soon established.

It is far from unfrequent for the pains present in uterine affections to lead to the belief of the existence of *Ovaritis*, in consequence of pain over the seat of the ovary, which is increased under pressure, and attended with the occasional drawing up of the muscles of the abdomen, so as to simulate a swelling. However, attention to the course of this pain will show that it comes from the lumbar region downwards and forwards to this part; that, upon moving the skin over the muscles beneath, the pain is recognised to be seated in these muscles, and hence is increased by pressure before this can have affected the organs deep in the pelvis. Nay, further, it often happens, that upon gentle pressure great pain is felt, but on increasing this pressure and carrying it deep into the pelvis, little or no pain is complained of. The pain is occasioned by the pressure on the abdominal walls, and its severity, like that of most nervous pains, passes off from a continuance of the pressure. It is, however, very distinctive of the ovary not being the seat of the disease.

What is the diagnosis between this disease and "*inflammation and ulceration of the neck of the uterus in the virgin female*"? On referring to the symptoms of ulceration, as detailed by Dr. Henry Bennet, we recognise, in the description which he gives, the same symptoms which existed in the present case. He states that these symptoms indicate ulceration; yet, in the case under consideration, no ulceration was present. Here then is a marked discrepancy. This case, in itself, is sufficient to shew that the symptoms, which are given as indicative of ulceration, do not indicate this morbid lesion, inasmuch as they here existed in a marked degree, and yet not a trace of ulceration was to be found. Too much, however, has been written on this subject to allow it to be discussed in this incidental manner. It would occupy more time than can at present be devoted to it; yet I may state, that there is not sufficient evidence before the profession to prove the existence of this morbid condition in the virgin female, and that the statements, which have been made respecting it, contain serious fallacies and errors.

Treatment. The eminent success which attended the treatment adopted in this case, is the best proof that it was the correct plan. It also satisfactorily proves, that chronic inflammation of the uterus and vagina will produce great languor and depression of the general system, loss of flesh, pain and fulness of the head, great disturbance of the nervous system, and disorder of the digestive organs; and that all these symptoms will pass away when the local cause which produces them is removed. For, under the influence of mild antiphlogistic remedies, directed to overcome the local disease, all these morbid signs passed away, and the patient gained flesh, lost the languor and depression, recovered her natural spirits, the power of sleeping soundly, and the appetite; in a word, was restored to better health than she had had for years. It would, however, be conveying a very erroneous impression, were it supposed that all cases yield thus readily to treatment. In many, the original disease has continued a sufficient length of time to impress a functional change on the nervous system; and this change will remain after the local disease, which produced it, has been removed. These are troublesome cases, and

require gentle narcotics with general tonics, and attention to the mental condition of the female. At other times, chronic inflammation is combined with an anæmic condition of the system, which constitutes a distressing combination. For, on the one hand, depressing remedies are required to subdue the local disease, and yet are contraindicated by the condition of the general system; whilst, on the other hand, the chalybeates, requisite to restore the condition of the blood, perpetuate and aggravate the local inflammation.

In the case under consideration, the application of leeches to the uterus itself was resorted to immediately. This was done in consequence of the long continuance of the disease, the severity of the pains, indicating a considerable degree of inflammation, and the general aspect of the patient, which conveyed the impression that local remedies were required in addition to the constitutional treatment. However, in the majority of cases with which I meet in practice, the local application of remedies is not required, as the disease yields, in a short time, to mild narcotics, combined with small doses of blue pill, or grey powder, at bed-time; giving, during the day, alkalies, with hydrocyanic acid, in a bitter infusion; these remedies being aided by rest, and the occasional warm hip-bath before going to bed. In a large number of cases it is even unnecessary to recommend the use of lotions, which are particularly objectionable to the virgin female. The application of a few leeches to the perinæum, after the appearance of the catamenia, followed by a warm hip bath, is a very efficient means of combating the local determination of blood in chronic inflammation of the uterus and vagina, combined with congestion of the veins of the pelvis; a condition of things not unfrequently met with.

The plan of treatment which consists in giving stimulating remedies to "bring on", as the phrase is, the catamenia, whilst narcotics are administered to relieve the pain which this treatment induces, is much to be reprobated, as being the means of perpetuating the disease. It is very true that, in many cases, similar remedies, aided or not by a change of air, will restore the debilitated constitution, and, by removing some of the effects of the disease, lead to the delusive hope that the disease itself is cured. But, unfortunately, after a little time the good effect of this treatment passes away, and the patient returns to the condition in which she was previous to this plan being adopted. It is, obviously, beginning at the wrong end. Another plan of treatment, which consists in considering the reddened mucous membrane of the lips of the uterus as an ulceration, and attempting to cure this by applying nitrate of silver, is so erroneous, and founded on so many false premises, that it is impossible to enter upon the discussion of it at this late period; I only notice it to record my dissent from the erroneous pathology which it includes, and from the improper practice which it inculcates.

9A, Langham Place, March 1851.

OBSERVATIONS ON SOME OF THE COMPLICATIONS OF HERNIA, AND ON OBSTRUCTION OF THE INTESTINE WITHIN THE ABDOMEN.[1]

By R. R. ROBINSON, Esq., M.R.C.S. Eng., late President of the South London Medical Society, and formerly Surgeon to the London Dispensary.

PART FIRST.

OBSERVATIONS ON SOME OF THE COMPLICATIONS OF HERNIA.

I TRUST I need not offer an apology for bringing the following cases before my professional brethren.

Hernia, from the suddenness of its appearance; the dangerous symptoms which may quickly follow; the rapidity with which it may destroy life; the delicacy of the operation which it often requires; the obscurity in which it is sometimes involved; and the beautiful illustration which it affords of the power of our art in arresting the ravages of death—ever has been, and ever will be a subject of deep interest to the surgeon. It is not, however, my intention to enter at large upon the intricate subject of hernia, but merely to offer a few observations upon some of its complications which have fallen under my notice.

I. STRANGULATED HERNIA—APPARENT REDUCTION—SYMPTOMS UNABATED. Cases occasionally occur, in which, after an inguinal hernia has been apparently reduced, symptoms of strangulation continue to increase, and lead to a fatal termination. This may be owing to two causes; either to the return of the intestine to the upper part of the inguinal canal, and not into the abdomen,—constriction, therefore, continuing at the internal ring; or to the return of the sac, together with the hernia constricted by it,—hernia reduced *en masse*. Of both of these varieties I am enabled to offer illustrations, for which I am indebted to my friend Mr. Luke.

CASE I. STRANGULATED INGUINAL HERNIA REDUCED EN MASSE—DEATH. A surgeon was called to a case of strangulated hernia, with well marked symptoms. The taxis was applied, the tumour disappeared, and the symptoms subsided, but returned in a few hours, and the patient died. Mr. Luke, who conducted the dissection, found a portion of mortified gut in the upper part of the inguinal canal. The hernia had been returned through the lower ring, together with its sac, at the neck of which the stricture was situated.

CASE II. STRANGULATED INGUINAL HERNIA REDUCED EN MASSE—DEATH. A labourer was admitted into the London Hospital, who was the subject of strangulated hernia. The hernia was relieved by the dresser, and all the symptoms subsided. The man did well. A fortnight afterwards, however, the hernia again descended, and again became strangulated. Upon this occasion the man *forcibly* returned it himself; the symptoms, however, became aggravated, and he died. Dissection showed that the hernia, with its investing sac, had been forced through both rings, the stricture still remaining upon it, and

[1] The substance of two papers read before the Physical Society of Guy's Hospital on March 10, 1849, and January 11, 1851.

seated at the neck. The whole had passed between the peritoneum and abdominal muscles, in a direction towards the bladder.[1]

II. Intestine adherent to the Sac. Where constriction takes place to such an extent as to excite inflammation, albumino-fibrine becomes effused, and a false membrane is formed, by which the intestine is glued to the sac. In these cases, there is very little if any serum secreted, and there is great danger, in operating, of wounding the gut; hence it is highly important to ascertain when this has taken place. Much may be learnt by pinching up the sac prior to opening it. If the sac is not adherent, it will feel thin between the fingers, and the contents will be felt to glide away; if it be adherent, the medium between the fingers will be thicker than can be supposed to arise from sac only, and no gliding will be felt. Cases III and IV, which were operated upon by Mr. Luke, which came under my observation, and which he has kindly permitted me to publish, are cases in point.

Case III. Strangulated Inguinal Hernia on the Right Side—Intestine adherent to the Sac—Operation—Recovery. A pavior, aged 55, subject to pulmonary disease, was admitted into the London Hospital on January 8th, 1828, under Mr. Luke. He had been subject to hernia for three months, but had never worn a truss. It had descended during a severe fit of coughing three days previously, and he had been unable to return it. The hernia was situated in the right groin; it was small, tense, painful on pressure, and devoid of impulse on coughing. Vomiting and hiccup were urgent, but there had been no motion. The warm bath and taxis being unavailing, Mr. Luke performed the operation. After dividing the integuments and some fasciæ, a membrane was brought into view, the nature of which was rendered obscure by numerous vessels running upon it in a circular direction; by pinching up a fold of it, however, between the finger and thumb, a globular body, evidently the intestine, could be felt underneath it. It was, therefore, cautiously opened, and proved to be the sac in a thickened state, having the intestine closely adherent to its interior by bands of recent lymph, which were most numerous, and most thick about its neck. These were carefully separated with the finger. This stricture, which was very tight, and situated at the inner ring, was divided; a knuckle of small intestine (of dark colour, from congested vessels) was returned into the abdomen, and the wound was closed in the usual way. The symptoms gradually subsided, and the recovery was rapid.

Case IV. Strangulated Inguinal Hernia—Circular Direction of the Vessels of the Sac—Adherent Intestine—Operation—Recovery. D. Lazarus, aged 62, was admitted into the London Hospital, under Mr. Luke's care, on the 11th of February 1833. He had been seized, on the 8th, with violent cough, after which

[1] I hesitated much before alluding to this complication, after the able paper upon the subject by Mr. Luke, in the twenty-sixth volume of the *Medico-Chirurgical Transactions*. As, however, these remarks were penned more than fourteen years ago, long before that paper appeared—as I am indebted to Mr. Luke for acknowledging it—as it is a very important complication of hernia—and as, from cases subsequently published by Mr. Luke in the *Medical Gazette*, it would appear not to be so rare as some surgeons suppose, I have thought it best to let it remain as originally written.

he discovered a tumour in the right groin, which soon became painful. Towards evening his food returned; he was frequently sick, and had hiccup occasionally. These symptoms continued unabated at his admission, when a small globular tumour was visible in the right groin which was painful on pressure, but had no impulse on coughing; there were also pain and tension of the abdomen, and the bowels were obstinately constipated. After the usual attempts had been made to return the hernia, without success, the operation was performed by Mr. Luke. The integuments and fasciæ being divided, the sac was exposed. Its vessels were circular, and it had strikingly the appearance of intestine; and it was surrounded by cellular tissue and fat, which had very much the aspect of omentum. When the sac was pinched up, it appeared thick; the gut, upon the most careful examination, could not be felt to glide from underneath it, which led Mr. Luke to express an opinion, that the intestine was adherent. The part of the sac which appeared the *thinnest* was then carefully punctured towards the pubal side, when *one drop* of bloody serum escaped. Upon introducing a director, the intestine was found universally adherent to the sac (except where it had been opened), by red and easily separable adhesions. The very tight stricture having been divided at the internal ring, the gut, a fold of the ileum, in a state of engorgement, was returned into the abdomen. Two hours after the operation the bowels acted, the symptoms soon went off, and nothing untoward occurred.

Remarks. It is difficult to imagine a more embarrassing case than the last of these, or one in which the intestine was more likely to have been wounded, as the usual guides in doubtful cases were entirely absent. The bowel could not be detected when the sac was pinched up; and, had the latter been opened at the *lower* part, the spot usually selected, the gut could hardly have escaped; as the *only drop of fluid* was fortunately placed at the part where the opening was made. Although, upon pinching up the sac, the bowel could not be felt, the precaution was valuable; as I think it probable that it separated the adhesions at that part, and, if so, was instrumental in preserving the intestine from injury.

The *direction* of the vessels has been laid down as a guide to distinguish between the gut and the sac; the vessels of the former, it is said, run in a *circular*, the latter in a *straight* direction. In the cases alluded to above, the vessels of the sac were as circular as those of the intestine; and consequently no assistance was gained from that source.

III. Mortification of the Bowel simulated by the Effects of Tobacco. In some irreducible herniæ, especially in those irreducible from bulk, tobacco enemata have been occasionally used with success. They do not, however, always succeed; and when they fail, are injurious, as they tend to perplex the case, and, by greatly diminishing the powers of life, give rise to the idea that mortification has commenced. This is no mere supposition, but is illustrated by the following case.

Case v. Large long-standing Hernia—Strangulation—Collapse from the Effects of Tobacco—Operation—Reco-

VERY. A man, aged 55, the subject of hernia thirty years, was admitted into the London Hospital under the late Mr. Headington, the rupture having slipt from under his truss an hour previously. The tumour was large, tense, and painful. He was bled, and was put into a warm bath; by which means syncope was twice produced, but the rupture could not be returned. The pulse was at that time full and hard, and the tongue coated. The tobacco enema was tried, and repeated, after which the pulse became feeble, and his strength prostrated. The taxis was again unsuccessful. While under the tobacco influence, Mr. Headington visited him, thirty-two hours from the descent of the hernia. His countenance was much altered; it was shrunken, pale, and haggard; the pulse was small, fluttering, and intermittent; the tongue brown and dry; there was great thirst, and indifference to surrounding objects; and, although the abdomen was still tense, the tumour was flaccid, and could not be returned. Mr. Headington thought that mortification of the gut had ensued, that the case was hopeless, and that the man was *in articulo mortis*. Mr. Luke, who had witnessed the case throughout, suggested that the prostration did not exist prior to the use of the tobacco, and was referable to it. Upon this suggestion, Mr. Headington performed the operation, and with success.

REMARKS. Upon looking to the result of this case, there can be no doubt, although the symptoms much resembled those of mortification of the bowel, that the depression, under which the patient laboured, was owing to the tobacco. Nor can there be any doubt about the propriety of the performance of the operation; yet, had the operator followed his own opinion, he would have left the patient to his fate; the effect of which must have been delay, with the probability of a fatal result.

I may here allude to a case that came under my care some years ago, but the particulars of which have not been preserved, in which mortification of the bowel (in a gentleman, the subject of hernia, just returned invalided from India) was, in some degree, simulated by the collapse of jungle fever. He died, but I had no means of obtaining a *post-mortem* examination.

IV. PASSAGE OF FOREIGN BODIES THROUGH AN IRREDUCIBLE HERNIA. Although persons, with irreducible hernia, may pass many years without inconvenience, they are, nevertheless, in constant danger, when substances difficult of digestion, and irritating in their nature, are taken into the alimentary canal. A plum-stone, for instance, or more especially the stone of a peach, if accidentally swallowed, might, in such a person, be attended with very serious inconvenience. It is astonishing, however, what miraculous escapes sometimes occur. In proof of this I now refer to the gill-bone of a fish (?) (Fig. 1); it was very hard and sharp, and not only escaped being acted upon by the gastric juice and dissolved, but actually passed through an irreducible inguinal hernia, not only without any injury, but without the patient's knowledge; the first intimation which he had of it being a pricking sensation at the verge of the anus, from whence he withdrew it.

Fig. 1.

Persons, however, are not always so fortunate; for Sir Astley Cooper mentions the case of a boy, aged 13, admitted into St. Thomas's Hospital for irreducible scrotal hernia. He had an accident and swallowed a pin. Five weeks afterwards, the hernia began to swell and be painful. A poultice was applied; an abscess formed and burst, and, at the orifice where pus was discharged, the point of a pin projected; it was easily removed, but a fistulous orifice remained.[1]

V. Descent of the Bowel after Operation. If the hernia has been of long standing, and the rings have, in consequence, become enlarged, the hernia is liable to come down after the operation, and again become strangulated. Thus, in the patient mentioned in Case v, on the tenth day from the operation, the hernia came down, and was attended with pain and vomiting; the man was leeched, and put into the warm bath, when the symptoms went off, and the bowel gradually returned; so that by the thirteenth or fourteenth day it was entirely within the abdomen. On the thirty-ninth day from the operation, when he was convalescent, and about to leave the hospital, the bowel came down more than ever; pain, vomiting, and hiccup immediately supervened. He was again put into the warm bath, and bled to twenty ounces, by which means syncope was induced, and in a few hours the intestine was returned; shortly after which the bowels were opened; the pain, sickness, and hiccup, subsided, and he had no relapse. It is a curious circumstance, that the hernia, twice descending, should each time have threatened strangulation. The first time, as he was purged, its descent was probably owing to the action of the abdominal muscles; but for the second descent, there did not appear any adequate cause, as it occurred while he was sitting quietly in a chair. In another case that came to my knowledge, the strangulation was more complete, the operation was a second time performed, but the case was, notwithstanding, fatal.

Cases of this kind show the necessity for great caution in regulating both the diet and action of the bowels after this operation, and the absolute necessity of perfect rest in the horizontal position. Opium also, as recently advised by Mr. Cock,[2] may, in these instances, be sometimes beneficial.

VI. Double Hernia—Strangulation. It is not, I believe, very common, except in the inguinal regions, for two ruptures to exist in the same individual. A person may, however, be the subject both of an inguinal and of an umbilical hernia. Symptoms of strangulation may occur, and a doubt may arise to which hernia the symptoms are referable. Of this I am enabled, through the kindness of my friend Mr. Luke, to offer an illustration. I will first, however, advert to a case, detailed by Sir Astley Cooper, of a woman, admitted into Guy's Hospital with *three* herniæ; one at the navel, one at the right, and the other at the left groin. The umbilical hernia, and that in the left groin, were irreducible; that at the right groin felt extremely sore on pressure. A doubt arose as to which was the rupture requiring the operation; but, as the symptoms were not very urgent, the opera-

[1] Cooper, Sir A. P., Bart., Treatise on Hernia, Part I, p. 17.
[2] Cock, Edward, Esq., Guy's Hospital Reports, vol. vi, part 1.

tion was delayed. In the mean time the woman died. The tumour in the right groin was found to be an enlarged and inflamed absorbent gland, lying over an empty hernial sac. In the left groin was a portion of inflamed intestine, and at the navel was an irreducible omental hernia, which had suppurated. The intestines were adherent to each other, pus was interposed in some places, and a considerable quantity had been effused into that part of the omentum which was contained in the abdomen. Sir Astley observes, "this woman chiefly complained of pain in the right groin; and, if the operation had been performed, this would have been the tumour laid open".[1]

Case VI. Inguinal and Umbilical Hernia—Strangulation—Operation—Recovery—Sudden Death five weeks afterwards. Mr. Luke was called to a female who was labouring under an inguinal and an umbilical hernia, with symptoms of strangulation. Both ruptures were very tense and painful, both were devoid of impulse on coughing, and both were irreducible. The former was small, and was apparently contained in the inguinal canal; of the two it was the most tense, and could be obscurely felt though a thick layer of fat; he was hence induced to operate upon this one. He found, upon opening the sac, a portion of small intestine tightly strangulated; he divided the stricture, and returned the bowel. Relief followed, the symptoms subsided, and the woman perfectly recovered. While, however, in apparent health, she died suddenly five weeks afterwards.

Remarks. From the success which attended the plan adopted in this case, have we not a guide in future, should strangulation show itself in a person the subject of double hernia? May we not conclude that the hernia, which had existed the longest, and is the most tense, should be the one first subjected to operation. It is possible, however, that the rupture which had existed the longest may *not* be the most tense. In that case, I would be guided by the *tenseness* rather than by the *duration;* for I am inclined to think that, had the duration of the hernia in the preceding case been reversed, the inguinal would have been the one first strangulated, as there is more of tendinous structure, and therefore there is likely to be more compression in this than in the umbilical region.

VII. Unusual Direction of a Hernia. Embarrassment sometimes arises from the peculiar and unusual course which a hernia follows. Thus it is well known, that femoral rupture, by tilting over Poupart's ligament, sometimes simulates inguinal hernia. Inguinal hernia also, when direct, is sometimes placed underneath, sometimes between the spermatic vessels. The peculiarity to which I am about to allude, is not, I believe, generally known; it is the passage of the hernia, after presenting at the internal ring, *upwards* and *outwards* towards the anterior superior spinous process of the ileum, instead of *descending* along the inguinal canal. For a knowledge of this fact, I am again indebted to Mr. Luke. This peculiarity occurred in the preceding case (VI). On exposing the hernial sac, by cutting the tendon of the external oblique, it was observed to proceed from below, upwards and outwards towards the spine of the ilium, contrary to the

[1] Cooper, Sir A. P. Treatise on Hernia, Part 1, p. 27.

course of the inguinal canal. From this arose a difficulty in getting at the stricture, which was surmounted by an assistant depressing the gut towards the pubis, and thus exposing the seat of stricture. There was but little difficulty in returning the gut, when the stricture was divided. Mr. Luke also conducted the *post-mortem* examination of a case where the surgeon, after repeated efforts (having opened the sac), had failed to return the gut into the abdomen. The dissection explained the cause of the difficulty. The sac was found, after passing through the internal ring, to pass *upwards between the muscles*, as well as in its usual course through the inguinal canal to the pubis. The internal ring, therefore, might be said to be opposite to the centre of the sac. The embarrassment, then, arose from the gut, when pressed at the pubal extremity of the sac, being received into that which might be called the ilial extremity, instead of being returned through the ring into the abdomen; and, on remission of pressure, returning to its former position at the pubis. From the case not being understood at the time of operation, the hernia remained unreduced.[1]

VIII. Peritonitis coexistent with Hernia. When a hernia becomes strangulated, inflammation is quickly set up in the peritoneal coat of the bowel, and sometimes spreads with rapidity through the entire peritoneum. Peritonitis and hernia are, therefore, very frequently combined. The former, however, is usually subsequent to, and caused by the latter; but it occasionally happens, that peritonitis occurs in a subject of hernia, in which the hernia is in no way implicated as a cause. By the combination of the two, however, much obscurity may arise. Of this we have an illustration in the following case.

Case vii. Reducible Inguinal Hernia on the Left Side—Peritonitis—Ulceration of the Mucous and Muscular Coats of the Bowel—Death. A man, aged 60, after having been exposed to wet and fatigue, and after having been unwell for a fortnight, was seized with rigors at irregular intervals, constipation of the bowels, and pain in the abdomen; but, the day before he came under my care, he had had three motions, which were described as scanty, and pale coloured. He was bled, leeched, and treated with calomel and opium, and aperients. At my second visit, the pain had been somewhat relieved; and, upon close examination, I discovered a tumour in the left groin, which he had never mentioned, but which he now stated to have existed eight years. It was returned easily, and with a gurgling noise, into the abdomen, when gently pressed. The tumour soon reappeared, the symptoms increased in severity, and he died the following day.

On inspection, the tumour in the left groin was found to consist of an old hernial sac, containing a portion of omentum, not gorged, and some serum. There was general peritonitis: about a quart of seropurulent fluid was found in the abdomen, with flakes of lymph, by which several of the convolutions were glued together. The jejunum

[1] See, upon this point, observations by Mr. Cock in Guy's Hospital Reports, new series, vol. v.

and upper folds of the ileum were very much distended with flatus. Six or eight inches of the latter intestine towards the cæcum were more flaccid than the rest; at one spot, ulceration had taken place through all the coats, but the contents of the gut had been prevented from escaping by adhesion to the surrounding parts, which had, however, become so softened, that yellow fæces escaped upon the least pressure. Several small vascular ulcers were seen in the mucous membrane of the lower part of the ileum.

Remarks. From the facility with which the hernia was reduced, and the entire absence of anything like constriction, either upon the intestine or omentum after death, it is clear that there was no *strangulation*, and that the peritonitis did not arise from that source. I think it was entirely unconnected with the hernia; and, from the patient suffering from rigors, pain in the bowels, constipation, and sickness, as well as from the ulcerated state of the intestinal mucous membrane, I believe that it was of a chronic character, and had been going on for some time.

I should have remained in complete ignorance of the hernia, had I not accurately explored the abdomen. This points out the necessity of doing so in all cases of abdominal inflammation—a custom which I generally adopt. From a conviction, however, that this was a clear case of peritonitis, I did not suspect the hernia, nor detect it until my second visit. The delay was in this case of no consequence; had, however, the peritonitis masked a hernia, it might have been otherwise, and a few hours might have proved very important.[1]

IX. Reducible Hernia in one groin—an Irreducible Tumour in the other—Peritonitis. In the preceding case, the reducible condition of the hernia left no doubt as to the propriety of treatment. The one to which I will now advert was, however, involved in great obscurity, and caused at the time much interest.

Case viii. Reducible Hernia in Left Groin—Irreducible Tumour in Right Groin—Symptoms of Strangulation—no Operation—Death from General Peritonitis. A Welshman, aged 80, was brought into the London Hospital. He was unable to speak a word of English; but, by means of an interpreter, it was ascertained that he had been the subject of herniæ in both groins sixteen years, which were easily reducible. Three weeks before his admission, he perceived a swelling in his right groin, which he could not return. It appeared suddenly, while he was in a passion. Upon examination, a hernia, easily reducible, was detected in the left inguinal region; and in the right groin there was a tumour, the size of a small walnut, circumscribed, unyielding, very hard and painful, the pain being increased on pressure. He had had a slight motion on the morning of admission, but none before that for *three* days, and none before that time for *ten* days. There was no impression made on the tumour by coughing; the abdomen was very tense, and painful on pressure; there was vomiting, which had existed *eighteen* days, and hiccup at times; the countenance was expressive of anxiety, the tongue dry and red,

[1] Vide Case xi.

the pulse small and wiry. Leeches were applied; he was put into the warm bath, and took calomel and opium in small doses, with salts and peppermint. No impression was made upon the tumour, but the bowels were freely opened. A consultation was held: the case was regarded as one of omental hernia, but the bowels having been freely opened was considered as a sufficient reason for not performing any operation. The bowels continued to act; but the vomiting, hiccup, and other symptoms increased, and the patient died fourteen days after admission.

Dissection. The peritoneum covering the abdominal parietes was very much inflamed, as was also that covering the intestines. Four ounces of serous fluid, with flakes of lymph, were found in the cavity of the abdomen. The folds of intestine were glued together by bands of lymph, easily separable. The hernia on the left side had returned, and appeared to have consisted of a portion of the descending colon, part of which was adherent to the internal ring. The tumour on the right side appeared to consist of the remains of an old hernial sac. The fold of peritoneum constituting this sac was very much thickened, and contained a substance resembling cartilage.

Remarks. Was not the peritonitis in this case independent of the hernia? It is clear from the *post-mortem* examination, that an operation could have availed nothing; yet it is questionable, whether the bowels having been opened was a sufficient reason for not operating. It is true that the *bowel* could not have been *completely* obstructed; but the omentum might have been imbedded in the sac, and might have been the cause of the symptoms. An operation in that case might have been attended with benefit. With the exception of constipation, the symptoms of strangulation were strongly marked; there were vomiting, hiccup, tension both of the tumour and abdomen, pain increased on pressure, and a want of impulse on coughing. Under these circumstances, a surgeon would, I think, be justified in examining the nature and state of the tumour.

X. Strangulated Hernia subsequent to Peritonitis. The complication to which I shall next allude, is one of a very distressing and serious nature. It is the occurrence of strangulated hernia, in a person who at a *distant* period had been the subject of general peritonitis, which had terminated by adhesions of the intestinal convolutions. Of this the following is a melancholy example.

Case ix. Strangulated Scrotal Hernia—Former Peritonitis—Operation—Descent of several adherent Convolutions which it was impossible to reduce—Death in twenty-seven hours. In a strong muscular man, aged 44, who had been from birth the subject of hernia, which was easily reducible, but for which he had never worn a truss, the rupture one morning descended, and he could not reduce it; he therefore applied for advice at the London Hospital. There was a large tumour on the right side of the scrotum, very tender to the touch; there was some tension of the abdomen, and he had had no motion for twenty-four hours. He was bled and put into the warm bath, and the taxis and tobacco enemata were tried, but all without avail, and without making any impression on the tumour. The symp-

toms increasing in severity six hours after these means were resorted to, the operation was performed by the late Mr. Harkness. Upon opening the sac, the hernia was found to consist of a fold of small intestine, the surfaces of which were adherent by bands of lymph of long standing. No sooner was the stricture divided (which was principally at the outer, although there was slight constriction at the inner, ring), than fresh convolutions, also adherent, descended, owing to the distended and tympanitic state of the abdomen. Notwithstanding well-directed efforts of twenty minutes' duration, these convolutions could not be returned; and so greatly had the tumour augmented, that the integuments would not cover it; the bowel was therefore protected by lint dipped in oil. Great pain, both of the intestine and abdomen, followed, together with vomiting and hiccup; the gut which protruded became very vascular and thickened, and in some parts covered with false membrane, while, in others, it was even granular. Great depression of the system followed, and the patient died twenty-seven hours after the operation.

Dissection. The passage from the sac to the abdomen was free. The peritoneum generally was highly vascular; the convolutions of the intestines were much congested, very much inflated, and everywhere united together by bands of long standing; four of these united the folds inclosed in the sac.

Remarks. As the hernia was of large size, it would have been much better to have divided the stricture without opening the sac, as advised by several authors, and especially by Petit and Mr. Aston Key, and more recently by Mr. Luke. Had this plan been adopted, it is probable that life would have been preserved; at all events, much distress, both to patient and surgeon, would have been avoided. Had there been, instead of a *large* hernia, only a *slight* protrusion until the stricture had been divided, and the sac opened, and then a fresh descent of the bowel had ensued, which it was found, partly from adhesion of the convolutions, and partly from the tympanitic state of the abdomen, impossible to reduce—what should have been done? The only alternative seems to be puncturing the gut; by this means the flatus would be got rid of, and the bowel so far diminished in size as to allow of its being entirely covered with the integuments, if not passed into the abdomen.

XI. Enlargement of the Inguinal Glands coexistent with Strangulated Femoral Hernia. In femoral hernia, obscurity may arise from enlargement of the inguinal glands. The hernia may become strangulated, and may subsequently return into the abdomen; a tumour and some symptoms of strangulation may nevertheless remain,[1] as in the following case, which was rendered still more embarrassing by other disease.

Case x. Abortion—Uterine Hæmorrhage—Enlargement of the Inguinal Glands—Strangulated Femoral Hernia—Disease of the Stomach and Cholera? I was requested by my

[1] See an interesting case in point by Mr. Else, *Medical Observations and Inquiries*, vol. iv, p. 355.

colleague at the London Dispensary to visit, on July the 14th, 1833, Mrs. M. A., aged 31, who had been admitted as a patient under his care on the 7th, to whom I am indebted for the following particulars. About seven weeks previously, she had miscarried; flooding had supervened, and continued some weeks, but was stopped in two days by rest and sulphuric acid. On the 13th, finding herself quite well, she went out, after which she was seized with incessant vomiting; the matter vomited amounted to *five or six quarts*. It was chiefly a turbid fluid, possessing a strong smell, much like that perceived upon opening the abdomen of subjects recently dead, and annoyed her greatly in passing. She complained of pain across the abdomen, which seized her at very short intervals, and then went off; her pulse was 132 and feeble; her countenance anxious. She had had no motion since the attack. On inquiry, it appeared that she had a small tumour on the inside of the left thigh; it was entirely devoid of pain, and had not the least impulse on coughing; it was very irregular, and had much the feel of an enlarged gland. There was no tension of the abdomen, nor the least abdominal pain on pressure; no hiccup. Her voice had the peculiar sound of cholera, and the depression appeared to me to be of that character. Taking all circumstances into consideration, I was impressed with the idea, that either there was not hernia, or that, if there was, the contents of the sac had returned. I suggested the administration of salts and peppermint water, to which in the evening calomel and opium were added.

On the 15th, we found that the vomiting had continued, and that she had passed neither motion nor urine. Her features were contracted and of lead colour, the fingers bent, the nails blue, the extremities cold, and the pulse imperceptible. It was the decided impression of two physicians who saw her, and of myself, that the case was one of Asiatic cholera. The effervescing mixture, with ammonia, was given, and brandy and spiced beef-tea administered; but all to no purpose, as she died at five o'clock in the afternoon.

Dissection. Putrefaction was fast advancing. The abdomen was very much distended; no flatus, however, escaped upon opening it. The stomach and small intestines, to within the lower third of the ileum, were thickened and very considerably distended with a light drab coloured fluid, which, upon removal, half filled a bucket. The mucous membrane of the stomach was very vascular, and in some parts covered with an apparent false membrane, which separated by maceration. In two places there were large black spots, which at first looked like sloughs; but, upon closer inspection, the membrane did not appear destroyed. It was, however, far from healthy; it was rough, devoid of villi, and in places studded with spots, some of black and others of yellow colour. Upon examining the left groin, there was discovered a small hernial sac devoid of contents, covered by one of the inguinal glands, much larger than common (Fig. 2). Lying just above the inner ring, was a portion of the ileum, about one-third from its termination in the colon; part of the calibre of this was of a deep purple colour, and appeared as if it had been the subject of strangulation (Fig. 4). Below the constricted part, both the small and large intestines were empty. The other abdominal viscera were healthy.

Fig. 2. Shows an inguinal gland enlarged, and lying over the hernial sac.*

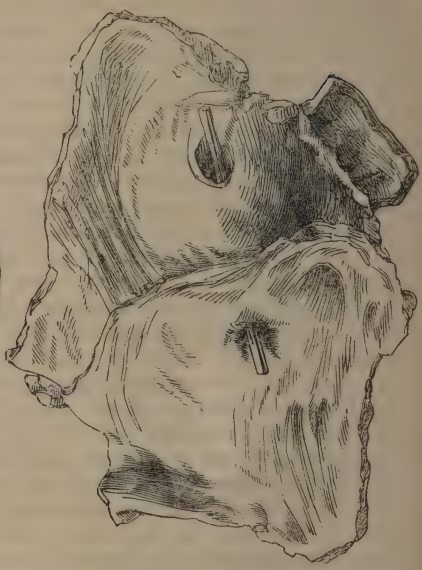

Fig. 3. A posterior view of the former preparation, showing the opening of the sac and the femoral vein upon its inside.

Remarks. The first point which attracts attention in the preceding case, is the number of maladies under which the patient laboured, viz.: abortion, uterine hæmorrhage, enlargement of the inguinal glands, femoral hernia, disease of the stomach, and cholera.

We are naturally, in the next place, led to ask, which of these last was the primary affection? In an illness of little more than forty-eight hours' duration, so soon attended with depression of the whole system, it is difficult to solve this question. It is not improbable, that chronic disease of the stomach might have been going on unnoticed for some time, by which perhaps she was rendered more liable, upon exposure, to be attacked by cholera; and that the great straining, which attended the effort to vomit, might have forced down the hernia. The hernial contents—a portion of small intestine—had become in some degree strangulated, as was evident from the engorgement of the intestine at one spot.

It may, in the third place, be asked, whether the intestine was down at the time that I made an examination of the tumour? This it is difficult, if not impossible, to determine. The *post-mortem* examination induced me to think that it was not, and justified, I think, the course which I adopted; the inguinal glands were evidently augmented; the tumour was quite as large after death as before; and the portion of intestine strangulated was found *within* the abdomen, and, although congested, its structure was not at all disorganized. It is, therefore, probable that the constriction was not of long duration.

* The accompanying wood-cuts have been executed by Dr. Westmacott, of King's College, from preparations in my possession.

That this woman was suffering from the influence of cholera, I infer from the *urgency* of the vomiting—the peculiar appearance of the fluid, and the *immense* quantity of it accumulated, with which the greater part of the small intestines was completely filled, notwithstanding the large quantity ejected—the peculiarity of the countenance and voice—the loss of pulse—the scantiness of the urine—the lividity and shrivelled state of the fingers and nails—and the conviction on the minds of three medical men, that such was the nature of the affection. Although diarrhœa, one of its characteristic symptoms, was absent, that does not prevent the disease from being cholera, as I believe that unequivocal cases of cholera have occurred without it; and the constriction upon the intestine sufficiently explains its absence in this case.

Fig. 4. The portion of intestine which had been incarcerated; the dark part representing the degree of engorgement that had taken place.

Since cholera has been raging in this country, it has been observed that many chronic maladies have apparently terminated fatally in cholera collapse. I have related in the *Medical Gazette* a case of long-continued hæmorrhage from the bowels, which was fatal in this way.[1] I have since seen a case of acute gastritis, with slough of the stomach, produced by oil of vitriol, which was attended, previously to death, with many cholera symptoms; and more recently still I have narrated in the same periodical[2] an extraordinary case of abdominal hæmorrhage, which was supposed to have been one of cholera; and I have alluded to a case reported to the Registrar-General as one of spasmodic cholera, but which, upon *post-mortem* examination, proved to have been hæmorrhage into the stomach from rupture of the gastric artery; but I have never before seen symptoms of cholera in conjunction with hernia.

XII. Strangulated Femoral Hernia—Rapid Collapse, supposed to be Cholera. Strangulated hernia, especially occurring in aged people, is frequently unattended with much pain; and is very likely, therefore, unless the surgeon be on his guard, to be overlooked. More than one case of this sort has come to my knowledge; and of this the following is an example.

Case xi. Strangulated Femoral Hernia—very copious Bilious Vomiting—sudden Collapse—Death in Thirteen Hours. A woman, aged 63, very sallow looking, thin and feeble, who had several times been under medical care for severe bilious attacks, accompanied with much exhaustion, and twice for hæmatamesis, sent for a medical man in haste one morning about eight

[1] Medical Gazette, vol. xiv, p. 137.

[2] Ibid. vol. xlii, p. 981.

o'clock. She was apparently quite well the preceding night, and playing at cards in high spirits, although she had had occasional pains in the back and lower part of the abdomen, and felt sick; but these symptoms went off, and she made a hearty supper. She was seized in the night, and again about six in the morning, with violent vomiting, having brought up nearly a chamber-potful of green bile. She was greatly exhausted, sensible, but able to speak *only* in a whisper. The face, particularly the nose, and the hands (especially the right, which she had out of bed), were quite cold. She had cramps in the legs; *no* pain in the abdomen. She had had *one motion the preceding day; and she remarked how regular her bowels had been lately*, and that without medicine. She was naturally of costive habit. No urine had passed. Ten grains of calomel were given immediately; sulphate of magnesia and sesquicarbonate of ammonia, with peppermint-water, were ordered every four hours; fomentations were applied to the calves of the legs, and beef-tea and brandy administered.

At 2 P.M. she had been several times sick; the matter now rejected was said to have been very offensive when passed, but was without smell when shewn to the medical attendant; it was of the colour and consistence of thick gruel, with a reddish-brown tinge. She was in a state of perfect collapse; there was no pulse at the wrist; the nose, face, and hands, particularly that out of bed, were very cold; there were violent cramps in both legs, which were drawn up in knots. A scruple of calomel was given immediately; half a drachm of aromatic spirits of ammonia was ordered to be taken every four hours; friction with mustard was applied to the legs; and the beef-tea and brandy were continued.

At 4 P.M. she seemed decidedly better. She was quite sensible and cheerful; had been sick only once; and had passed some urine, but in no great quantity. The abdomen was not distended, or tender on pressure; her skin, to the hand, was quite cold, although she said that to her it felt warm; there was no pulse at the wrist, but the cramps were gone.

She sank soon afterwards, however, and died at 7 P.M., thirteen hours from her first seizure. Upon finding her dead, the *possibility* of hernia crossed the surgeon's mind, and he examined the groins, when he perceived in the right a swelling of small size, equal, and very tense, pressure making no impression upon it. Upon making inquiry if she had been afflicted with rupture, her friend, who, singularly enough, was the subject of that malady herself, replied in the negative; and said that the patient had often congratulated herself that she was not thus affected. She was a woman of very weak digestion; and it was ascertained that she had lately been eating freely of pork, veal, and rabbit-pie.

DISSECTION, seventy-five hours after death: weather muggy, but cold. Putrefaction was commencing. The tumour was still very tense. Nothing was wrong in the chest. The liver was pale; there was some green bile in the gall-bladder. There was *central contraction of the stomach;* the intestines generally were slightly red; the *spleen* remarkably *small* and *black;* about three drachms of bloody serum were found in the abdomen. A femoral hernia existed on the right side; the stricture embraced very tightly a piece of ileum of the size of a nut.

(Figs. 5 and 6.) This strangulated intestine was of slight red colour; about two feet of ileum, a little above the strictured portion, were very much enlarged and distended, with reddish-brown looking fluid; the mucous membrane here was blackened from venous congestion. The other parts of the small intestines were contracted; the cæcum and colon natural. There was only a drop or two of fluid in the sac, and no effusion of coagulated lymph.

Fig. 5. Represents the small femoral hernia, the sac opened, the intestines congested, the femoral artery and vein with the vena saphena entering it.

Remarks. This case affords scope for many important inquiries. In the first place, it shows the great importance of an accurate examination of the abdomen, in all cases of serious interruption to the function of the gastro-intestinal canal. The surgeon was thrown off his guard, by having so often before attended this patient for biliary derangement. The very large quantity of bilious fluid vomited, clearly shewed that she was bilious now. There was a good deal of cholera in the neighbourhood at the time, and the case had comparatively few of the symptoms of hernia about it. The bowels had been open the previous day; there was neither pain nor tension of the abdomen, and there were symptoms not at all usual in hernia; pains in the back, cramps of the legs, and *copious* vomiting, together with collapse so severe and so rapid that the patient was dead in thirteen hours from the attack. I do not remember to have seen a case of hernia so rapidly fatal; and

patients have often recovered from operation, after strangulation of many days' continuance.[1]

Fig. 6. Exhibits the posterior view of Fig. 5; the intestine is seen entering the sac and firmly strictured by it; also the course of the epigastric artery on the outside of the sac.

Sudden collapse has been so generally associated with cholera, that I feel persuaded that association has led many persons into error, as it did the surgeon in this case. Collapse is owing to a depression of the nerves of organic life; and whatever tends to depress that system, I believe to be capable of producing collapse in no wise different from that produced by cholera. If that impression be correct, it will do much to take from cholera collapse as a diagnostic sign. Although it is to be regretted that the hernia was not detected, I doubt if any thing could have been done to save the patient. The taxis, from the tightness of the stricture even after death, I feel persuaded would never have returned it; and, from the moment she was seen, she was much too weak to have allowed either a warm bath, a tobacco injection, or an operation to have been suggested. Had she been seen earlier, and the hernia then discovered, it is just possible that an operation would have saved her life; although, from the great rapidity of the collapse, the absence of inflammatory action, the comparatively little congested

[1] Sir A. Cooper states, that a case has been fatal eight hours from the first appearance of strangulation, and that an operation has been successfully performed on the eighth day.

state of the intestine strangulated, and the central contraction of the stomach, so often seen in those who die a sudden death, there seems ground for believing that her attack, from its very commencement, was mortal. The state of her spleen was worthy of attention; its small size, and the pale, thin, half nourished appearance that she presented, seem to favour the opinion of those, who believe the function of that organ is concerned in the development of the red globules of the blood.

Conclusions. Having now narrated all the facts which I have to bring forward, it only remains for me, in conclusion, to state the inferences that I have drawn from them, with regard to the occasional complications of hernia.

1. Symptoms of strangulation may continue after a hernia has been apparently reduced—the reduction *en masse*, as it has been called. This may be owing to one of two causes; either to the return of the intestine to the upper part of the inguinal canal, and not into the abdomen, constriction therefore continuing at the internal ring; or to the return of the sac, together with the hernia constricted by it.

2. The intestine may be universally adherent to the sac. It is very important to ascertain this, and much may be learnt by pinching up the sac.

3. The direction of the vessels cannot be relied upon as a distinguishing mark between the intestine and the sac.

4. Mortification of the bowel may be simulated by the effects of tobacco; and, in doubtful cases, an operation ought to be performed.

5. Mortification of the bowel may be simulated, in some degree, by the collapse of jungle fever.

6. Foreign and irritating bodies *may* pass through an *irreducible* hernia without any ill effects.

7. The bowel may redescend after operation, may again become strangulated, and again require operation.

8. Strangulation may occur in a person the subject of double hernia; and a doubt may arise as to which is the hernia requiring operation. In such a case, the hernia that has existed the longest, and is most tense, should be the one first subjected to the knife.

9. A hernia may pass in an unusual direction.

10. Peritonitis may be coexistent with hernia, in cases where the latter is in no way implicated as a cause.

11. There may be a reducible hernia in one groin, an irreducible hernia in the other, and peritonitis.

12. Strangulated hernia may occur subsequently to peritonitis. If this could be known, it would be very desirable not to open the sac; if it be opened, and numerous adherent convolutions descend so as to prevent their being covered by the integuments, the gut should be punctured to diminish its contents.

13. Enlargement of the inguinal glands may be combined with strangulated femoral hernia, and cause great obscurity.

14. Strangulated femoral hernia in old, irritable, and weak persons, may be rapidly fatal from collapse, scarcely, if at all, to be distinguished from that which accompanies malignant cholera.

Camden Row, Camberwell, April 1851.

(To be continued.)

ON THE DIAGNOSIS OF INFLAMMATORY DISEASES OF THE CERVIX UTERI;

AND ON THE USE OF POTASSA FUSA OR POTASSA CUM CALCE IN THEIR TREATMENT.

By J. HENRY BENNET, M.D., late Physician-Accoucheur to the Western General Dispensary, etc.

(Read before the Medical Society of London, April 11, 1851.*)*

It is not my intention in the following paper to enter at length into the consideration of the symptoms of Inflammatory Disease of the Neck of the Uterus, but merely to give a brief and concise analysis of those symptoms, and of those moral rules which guide me in the cases requiring surgical examination and treatment. In the second edition of my work on *Uterine Inflammation*, I have already described the semeiology of these affections at such length, and with so strict an adherence to nature, that it would be mere repetition to do more. Indeed, although I have now had several years' additional experience since it was written, I find that I have but little to add, and nothing to alter.

The discussions which have taken place in this Society during the present session, have painfully convinced me that a less elaborate and more concise statement of the rules which I follow myself, and which I have laid down in the above-mentioned work for the guidance of others, in the diagnosis and treatment of these diseases, is required to justify my practice. My name and authority have been positively appealed to, as a sanction for the surgical scrutiny of the uterine organs of many hundred females who had no uterine disease; and this extensive scrutiny appears only to have led to the discovery of a limited number of instances of disease, so slight as to give way to mere injections and general treatment. Now I must be allowed, before I proceed, most emphatically and most solemnly to repudiate any connexion, as an author or as a practitioner, with such unheard of and such unwarrantable practice. The rules of diagnosis which I have given are meant to lead to the recognition of positive disease, and not to sanction the satisfaction of a morbid curiosity as to the state of organs, which there is no excuse for bringing into view by surgical means, unless we have the conviction that they are the seat of disease, and of disease not to be cured by other than surgical appliances. That the conscientious application of these rules by all practitioners, imbued with a due sense of the great responsibility of their position, does lead, all but invariably, to the recognition of such disease, is proved by my experience, and by that of hosts of talented practitioners, whom I may claim as converts to my views, and whose names I could mention, were it necessary. I may safely say, that I do not make an instrumental examination of the uterine organs once in six months, without finding sufficient disease to justify the step, so careful am I first, by oral inquiry, to be all but certain that disease really exists. Indeed, the mistakes I myself make are generally on the other side; for it not unfrequently occurs, that after treating a patient in vain by general means for several months, without making a surgical examination, on account of the obscurity of the local symp-

toms, I at last find a key to the failure in the existence of local disease, which I did not at first consider myself warranted in looking for. That such will generally be the case I am convinced, however fully the pathological views I defend may be adopted,—at least with all conscientious practitioners, who treat with due respect the females who entrust themselves to their care; and who, acting thus, are as careful and as mindful of the delicacy and the feelings of the patients who come under their notice as claimants on the funds of medical charities, as of those belonging to the higher ranks of society. With a conscientious observance on the part of the profession of those moral scruples which guide surgeons in all painful and repulsive surgical examinations, such, for instance, as that on the bladder for stone, or on the rectum for polypus or fistula, there will be always more risk of uterine disease being overlooked, than of undue interference with the female organisation.

It is for the heads of the profession, for those who take upon themselves to guide their fellow practitioners, to prevent *abuse*, by accepting the legitimate and rational *use* of those surgical modes of exploration and treatment, which modern research has proved to be absolutely necessary to restore the uterine organs to integrity, in a very numerous and distressing class of diseases. This few have as yet done. Some, appealing to their past experience, which, however extensive, is in reality valueless, when brought to bear on newly-developed pathological facts with which they were unacquainted at the time it was gained, have boldly and openly negatived the facts and doctrines I have brought forward; others have attempted to investigate the subject, but, for want of practice in the necessary instrumental explorations, have often failed to detect disease when present,—a circumstance which I am continually seeing exemplified; whilst one or two, by an indiscriminate and senseless abuse of these means of exploration, have fairly exposed themselves to the inculpation of having abused them to an extent of which the records of the profession, either at home or abroad, can afford no parallel. Craving indulgence for these preliminary remarks, I will now proceed to the consideration of the subjects upon which I more especially wish to dwell.

The cervix uteri and its cavity are lined by a mucous membrane, highly organised, and abundantly supplied with mucous follicles, which is very liable to take on inflammatory action, like all other functionally exposed mucous membranes, and to subsequently become the seat of inflammatory ulceration. This important pathological fact, which has only recently been brought to light on the continent by the instrumental exploration of the organ, was not acknowledged or acted upon in this country, when I first drew the attention of the profession to it some years ago. At the same time, its recognition is of the most vital importance to science and humanity, as, in uterine pathology, all is and must remain in inextricable error and confusion, if it be repudiated. The frequency of ulceration in this region, in well marked cases of disease, as compared with other uterine lesions, is, indeed, so great, that out of 243 cases of inflammation of the uterus or its neck, treated by me at the Western General Dispensary, and given at the end of my work, ulceration of the latter part existed in 222. The

explanation of the frequency of ulceration in the cases examined by me is to be found in the facts, firstly, that slight fugitive catarrhal inflammation in this region often no doubt occurs, but without giving rise to sufficiently marked symptoms, local or general, to warrant any kind of local examination at the hands of a really scrupulous observer, such as I trust I may claim to be, and consequently is not often seen by him; and, secondly, that when inflammation does not subside spontaneously, it is aggravated by each successive menstrual congestion,—menstruation feeding uterine inflammation, and exercising a most pernicious influence over it in the great majority of cases; and thus is called into action the peculiar liability to ulceration presented by this mucous membrane. The tendency in this region to the perpetuation of inflammatory and ulcerative disease, when once it has manifested itself, is certainly most remarkable; it is greater even than in the fauces, and impresses upon the inflammatory affections of the cervix and its cavity many of their peculiar characteristics. Indeed, it is owing to the obstinacy, and to the intractable nature of the disease in those cases which alone ought to come under the *eye* of the practitioner, that surgical appliances, and consequently surgical examinations, become necessary.

The symptoms presented by patients suffering from inflammation and inflammatory ulceration of the cervix uteri, may be summarily divided into local and general. The local symptoms are: pains in the lumbo-dorsal, ovarian, and hypogastric regions, and down the thighs, with, in some instances, difficulty of walking; a sensation of bearing down on standing or moving; vaginal discharges; modifications of the menstruation, giving rise to dysmenorrhœa, menorrhagia, or amenorrhœa; constipation or diarrhœa; and irritability of the bladder. The general symptoms are principally dyspeptic, neuralgic, and hysterical conditions; entailing, secondarily, defective general nutrition, and consequent debility and anæmia.

All these symptoms, local and general, have been analysed so minutely in my work on Uterine Inflammation, that it is unnecessary for me to do more than to enumerate them. Were they always combined in each patient, nothing would be easier than the diagnosis of the disease; but such is by no means the case. Sometimes well marked local symptoms of disease will exist for years, without any general reaction, the general functions and health resisting and remaining good. In other instances, with the same amount of disease, there will scarcely be any local evidence of its presence, but the health will fail from the first, the disordered general condition resisting every means of treatment, until the local disease be treated and removed. These are the difficult cases in practice. From the extensive connexion between the nervous system of the uterus and other parts of the sympathetic and cerebro-spinal systems, the general morbid reactions to which disease of the uterus may give rise are protean. There is scarcely an organ in the economy, or any portion of the cerebro-spinal nervous system, which may not be sympathetically affected when uterine disease, and more especially inflammatory ulceration of the cervix, exists. Such being the case, it behoves us, in chronic general derangement of health in the female, not to omit analysing the state of the uterine organs; and, if the general morbid condition prove intractable, not

yielding to those medicinal and hygienic means which, in such conditions, are *habitually successful*, we are warranted in suspecting uterine disease, and in investigating the state of the uterine organs, provided one or more of the local symptoms enumerated be decidedly and constantly present.

If, in obscure cases, these elements of diagnosis are conscientiously and carefully weighed and acted on, without rashness or precipitation, the patient having the benefit of any doubt,—that is, being first treated generally, and by simple local means, such as injections, etc., if the local symptoms are so slight as to render the existence of decided uterine disease dubious,—very few errors of diagnosis will be committed, and very few females will be submitted to surgical examination who are free from disease, or only present such slight morbid conditions as not to require surgical assistance.

Were inflammatory and ulcerative disease of the cervix always limited to the external region of the uterine neck, and were it always discovered and treated before induration and hypertrophy had taken place, and before the ulcerative process had become chronic and confirmed, simple non-surgical means of local treatment, and attention to the general health, would no doubt suffice to cure the greater number of those so affected. But such is very far from being the case. Owing to the frequently obscure nature of the local symptoms, and to the length of time during which the disease may exist before it reacts sensibly on the general health, it has generally long been present when complained of and discovered, and has thus become so deep-seated and confirmed, and has given rise to so many structural changes, that surgical treatment alone can remove it; and hence the unavoidable necessity for the use of the speculum, in aid of treatment as well as of diagnosis. Moreover, there is an important feature in the history of these affections, which would be of itself sufficient to convince the most prejudiced of the necessity of surgical interference, were they to carefully observe nature, and not merely to reason on past experience, which, as I have already stated, is useless when new facts are brought forward. I allude to the circumstance of the inflammatory and ulcerative element, in the immense majority of cases, passing into the os and cervical canal. Owing to this very general extension of disease to a region which is beyond the reach of mere injections, these latter remedies, the only efficient local means of treatment that can be used without instrumental assistance, are, as a general rule, powerless to eradicate the disease. Indeed, we might as well try to cure gonorrhœa in the male by merely washing the gland with medicated lotions.

When properly used, however, injections invariably do a great deal of good; they remove inflammation and congestion of the vulva and vagina, diminish and limit the cervical inflammation, and, in some instances, lead to the healing of the more external and exposed part of the ulcerated surface. If, at the same time, strict attention is paid to the digestive functions, and to the health generally, the patient generally improves; the leucorrhœa, if present, is arrested; she loses many of the symptoms from which she is suffering, or at least they become mitigated; and both she and her medical attendant think that the morbid state is subdued. As soon, however, as the patient is left to herself, the disease, which has only been modified, not cured, begins to regain the

ground it had lost. Each successive menstrual period aggravates the symptoms, and in the course of a few months, the patient finds herself as bad as, or worse than before she was treated. She then, probably, consults some other practitioner, leaving her former attendant in the happy belief that he has cured her.

To resume: the physical examination of the uterine organs may be not only warranted, but rendered necessary by the presence of the local or general symptoms enumerated. If all, or nearly all the local symptoms I have mentioned are present, the case is a model one, respecting the nature of which there can be no doubt; and, as the local lesions are nearly invariably such as to require surgical treatment, the sooner the state of the patient is thoroughly cleared up the better. If one only of the local symptoms is present, but constantly present, and in a marked manner, and general symptoms are met with which do not give way to properly conducted treatment, there is also sufficient reason to suppose that local disease exists to warrant an examination. The mere existence, however, of disordered general health in a female, of dyspeptic and nervous symptoms, of debility and anæmia, is no proof whatever that she is labouring under uterine disease. These conditions may be the sympathetic result of scores of morbid causes and diseases.

The practitioner having thus acquired, by a careful oral analysis of his patient's symptoms, or, if in doubt, by the test of treatment, the conviction that she is labouring under decided uterine disease, what is the next step to be taken? Is she to be at once examined with the speculum? Most undoubtedly, most unquestionably not, until the state of the uterine organs has been ascertained by a digital examination. The condition of the body of the uterus, its size and position, can only be ascertained by the finger; and this may also be considered the best guide as to whether an instrumental examination be required or not. As I have elsewhere stated, when the mucous membrane covering the cervix uteri is ulcerated, the ulceration nearly invariably occupies the circumference of the os into which it dips, and which is more or less patent. Simple inflammation also, passing into the cervical canal, expands and dilates the os. Hence we have a very valuable diagnostic rule, which is now my principal guide as to the necessity for a specular examination. The latter I consider indicated and warranted, whenever the os is sufficiently open to admit the end of the finger. When this is the case, there may be either ulceration requiring local surgical treatment, or inflammation passing into the cervical cavity, which also necessitates surgical appliances. I would likewise add, as requiring instrumental examination, the cases in which the finger detects marked induration and hypertrophy of the cervix. When these latter conditions exist, it is impossible to judge what precise course of treatment is to be followed, unless the diseased parts be brought into view. The open state of the os is a most invaluable guide as to the presence of inflammatory disease, and the fact of its being so ought to be generally known. It is mentioned by Pauly in his edition of *Lisfranc's Lectures*, but has been lost sight of by French writers, and is generally, if not always, only alluded to by them as a physiological condition, which it is not. It is only within the last few years, that I have myself appreciated its great importance as a means of diagnosis. The os uteri, in

the healthy state, is perceptible to the finger as it passes over it, but the finger, or even its tip, does not pass into it; and, if it does, we are warranted in suspecting disease, unless the patient be pregnant, or recently confined, or the uterus be aggrandised by the presence of a fibrous tumour, etc.

When an instrumental examination has been decided on, it must be efficiently made. Whatever speculum may be used, the result cannot be considered satisfactory, unless the entire organ be brought within the field of vision, and unless it be so illuminated by daylight that a speck of dust would be visible, on any part of its surface. If the os be very open also, a bivalve speculum will alone enable the practitioner to correctly examine the state of the parts. By the expansion of its valves, the open lips of the os can be separated so as to allow the eye to penetrate more or less into the cervical canal, especially if, at the same time, these lips are depressed or elevated with the uterine sound. For a practitioner to state that he is never able to bring into view the interior of the cervical canal, with the assistance of the above rules, when the os is morbidly open, is merely to acknowledge his want of surgical dexterity or practice. Such an assertion proves, at the same time, that a host of important lesions must have escaped notice.

The cases for examination having been thus properly selected, and the investigation having been carefully and efficiently carried out, we find that the lesions brought to light are those which characterise subacute and chronic inflammation of mucous membranes in any and every part of the economy, including ulceration, which is found to exist in the great majority of cases. This latter assertion has been contested and even denied, but without any real foundation. Some of those who have taken this position, have done so from positive ignorance; they have attempted to negative facts, the result of extensive and amply corroborated experience, without endeavouring to test those facts. Others, not able to deny the frequent existence of inflammatory lesions in this region, have asserted that these lesions are seldom or never ulcerative, and that they constitute a form of granular inflammation. No one as yet, however, has deigned to give a definition of what this nondescript granular inflammation really is. French pathologists, and myself, following in their footsteps, have described as granular inflammation of the cervix uteri, a morbid state characterised by chronic inflammation of the mucous membrane, and of the mucous follicles with which it is studded, without abrasion or erosion of the epithelium,—in a word, without ulceration. When the cervix presents this form of the disease, the inflamed and hypertrophied follicles stand out prominently, and give to the organ a kind of strawberry appearance. Some of these follicles are occasionally ulcerated, forming small separate aphthous sores; but this is rarely the case.

In common with the continental pathologists who have preceded me in the study of these diseases, I give the name of ulceration to a state characterised by the absence of the epithelium, as the result of a morbid action, and by the presence of erectile granulations, similar to those which cover all granulating sores or wounds healing by the second intention. It is of little importance whether these granulations are so small as to be microscopic, or so large as to be fungous; in both cases the morbid condition is identical; in both cases there is loss of

substance, although there may be no excavated surface or raised margin; although even the granulations may overtop the surrounding surface. Indeed, we see this occurring daily, in all suppurating sores on the skin, as well as in the deeper tissues. That there is loss of substance, becomes evident if a granulating surface like this is submitted to maceration after death, as is seen in a pathological specimen, consisting of the uterus of the young virgin female whose case I have narrated in my work. In the diseased region there is found evident loss of substance, an *excavated* ulceration of the mucous surface surrounding the os. The mucous membrane is absolutely destroyed in some places, and the proper tissue of the cervix underneath neatly dissected out. How it can be said that there is no proof before the profession of inflammatory ulceration of the cervix in the virgin, considering the publicity given to this case, I cannot conceive. Moreover, this case is not mine, but one supplied to me by my late colleague, Mr. Anderson, the senior-surgeon to the Western General Dispensary. I have no hesitation in saying that, in this instance, during life, the evident loss of substance was certainly concealed by the erectile granulations (pus and sanies-secreting), which cover all suppurating sores; and that, consequently, according to the "new pathologists", it would have had to be called a granular inflammation. In the wax model of inflammatory ulceration, the condition during life of such a surface is well demonstrated.[1]

That the views, which I have just explained, agree with the definitions of ulceration given by the most classical writers, will be evident to any one who gives himself the trouble to refer to them. Thus, to cite only two or three authorities, Samuel Cooper says, that "ulceration is the process by which sores or ulcers are produced in animal bodies"; Boyer, that "an ulceration is a solution of continuity of the soft parts, more or less ancient, accompanied by a purulent secretion, and kept up by some local or internal cause"; J. L. Petit, that "an ulceration is a solution of continuity, from which is secreted pus, or a puriform, sanious, or other matter."

With reference to inflammatory ulceration in virgins, I can only repeat what I have stated elsewhere, that I am never without well-marked cases under my care, and that, in the results obtained, these cases are amongst the most satisfactory that I am called upon to treat; young females, to whom life had been a burden for years, and who had lost hope, being frequently restored to robust health. I do not mean to say, for a moment, that such forms of disease are common, but that they exist; and, in large consulting practices, they must be not unfrequently met with. If I have myself seen so many, it is, no doubt, from the circumstance of my having been the first to direct the attention of the medical profession to the existence of such disease. Thence it is, that I am frequently appealed to in cases in which it is suspected. At the same time, I now most emphatically repeat what I stated when I first made my views known: that I consider that a surgical investigation, in such cases, ought to be adopted only as a last resource,—as one that ought not even to be thought of, until every pos-

[1] The diseased uterus, above referred to, and the wax model, were exhibited to the Society.

sible and available means of treatment has been tried, and has failed; and until it is evident that the patient is doomed to hopeless misery, unless the disease, which is known to exist, be brought to light and grappled with. Then, and then only, is the medical attendant authorised to contemplate such a step; and, even then, the responsibility is so great, that, as I have stated, it ought to be shared, and a consultation held, unless the practitioner be himself a consulting accoucheur, and sufficiently confident in his own experience and judgment to assume the entire responsibility of his conduct. This is the advice which I have ever impressed, in all my writings on the subject. I can also most positively say that, although I have treated many patients of this class, I have never made a physical examination in a virgin female, in a single instance, unless the patient had been treated in vain for years by others, or for months by myself, by means directed both to the uterine and to the general symptoms.

The treatment of the local element in inflammatory affections of the neck of the uterus, which I adopt, may be given in a few words; it is the treatment followed in all chronic inflammatory diseases situated in a position attainable by surgical means. If there be any acute or subacute inflammation present, it must be subdued by antiphlogistics and astringents. When once this has been accomplished, the morbid action still persisting must be modified and converted into healthy vital action by stimulants. Thus, in the first stage of treatment, we use emollients, leeches, and astringent lotions; in the second, we apply to the diseased surface caustics, in order, secondarily, to set up healthy action. The eschar, which they produce, is eliminated and thrown off by a process of vital inflammation, which tends to restore the healthy condition of the diseased surface. The intensity of the stimulant to be used depends on the chronicity and sluggishness of the disease, and on its resistance to therapeutic means. In recent and slight cases, the nitrate of silver is sufficient; but when the morbid state penetrates below the surface, and the submucous tissues are diseased and hypertrophied, it is generally insufficient, and stronger agents, agents which produce a greater reaction, are required. Then it is that the mineral acids should be used. Occasionally, however, even these fail when the disease has existed many years, and there is considerable deep-seated chronic inflammation and hypertrophy. It is in such instances that potassa fusa, or potassa cum calce, proves a most invaluable remedy; inasmuch as, by its means, any amount of vital reaction, that is required, can be obtained. Since I have known its use, that is, for the last fourteen years, I have not met with any case of inflammatory disease of the cervix which has not eventually given way. But it is more especially since I have simplified the application of potassa cum calce, by running it into fine cylinders, like those of nitrate of silver, that it has proved invaluable to me; inasmuch as it has thus been rendered nearly as easy of use, and as free from risk in application, as the nitrate of silver; moreover, it may thus be much more easily graduated at the will of the operator. I must, however, again impress on my hearers that I never apply potassa cum calce to destroy tissues, but merely to set up healthy eliminatory inflammation, under the in-

fluence of which, indurated and hypertrophied tissues melt and are resolved, and morbid surfaces become healthy and heal.

I was induced, some years ago, empirically to apply, with great caution, the smallest sized potassa cum calce cylinders to the cervical canal, in intractable inflammation, as a last resource; and with great success. This success I now attribute to the fact of its reaching, by its more powerful action, the inflamed mucous follicles which lie between the radiations of the arbor vitæ, and are thus subtracted from the influence of milder agents.

Potassa fusa was first introduced as a remedy in these forms of uterine inflammation by M. Gendrin of Paris, but had not been adopted by the profession when I left that city, nine years ago; although, I believe, it has since been more favourably received. I can myself claim the merit of having introduced it into practice in this country, and of having simplified its use as above mentioned. I am continually using it with proper precaution, avoiding scrupulously the acute or subacute stages of disease, and never meet with any accident. I may say the same, as far as I am aware, of the numerous practitioners who have adopted it, throughout the country, on my recommendation. I must, however, caution those who would use it inside the os, to apply it very gently, and to guard against the too great closing of the cervical orifice, as the surface touched heals. For want of these precautions, in several cases treated in the country, in which I have been consulted, the os uteri has been all but closed. The dilatation of the contracted os is always easily accomplished when this is the case, by means of graduated bougies; but each contraction had better be prevented by proper judgment and care in the first treatment of the patient.

9, Cambridge Square, Hyde Park, April 1851.

BIBLIOGRAPHICAL RECORD.

Annual Address delivered before the Hunterian Society of London, Feb. 19th, 1851. By John C. W. Lever, M.D., Physician-Accoucheur to, and Lecturer on Midwifery at, Guy's Hospital. Printed for the Author. 8vo, pp. 23. Southwark (London): 1851.

Puerperal Fever is the subject of this address; and it is very ably and very instructively handled by the author. Dr. Lever's opinions being those of an accurate, independent, and accomplished observer, and being based on a twenty years' experience, in a very wide field of observation, have special claims upon the notice of the profession. They coincide, to a great extent, with the views of Dr. Fergusson, as to the nature of the different forms of the disease; of Mr. Nunneley, as to the relationship between puerperal fever and erysipelas; and of Drs. Simpson and Henry Kennedy, as to the analogy between surgical and puerperal fever.[1] Dr. Lever emphatically reprobates the recklessness of those practitioners who attend women in labour, immediately after dressing erysipelatous sores, performing *post-mortem* examinations, or visiting those labouring under puerperal fever, or bad forms of erysipelas. He thus concludes his remarks on this subject: "So convinced am I of the contagiousness of this disease, that I confess I have no

[1] London Journal of Medicine for January 1851, p. 77.

sympathy for those who, with these indisputable facts before them, lose case after case, from being themselves the vehicles of contagion ; gladly received into homes where hope is budding, and all joyful anticipation, they but resemble the destroying angel, for, instead of mirth, congratulation, and merriment, they leave sadness, gloom, and desolation."

THE HISTORICAL RELATIONS OF ANCIENT HINDU WITH GREEK MEDICINE, IN CONNEXION WITH THE STUDY OF MODERN MEDICAL SCIENCE IN INDIA ; being a General Introductory Lecture, delivered June 1850, at the Calcutta Medical College. By ALLAN WEBB, M.D., Author of the *Pathologia Indica ;* Surgeon in the Bengal Army ; Professor of Descriptive and Surgical Anatomy. pp. 34. Calcutta : 1850.

THIS is an introductory discourse which was delivered by Professor ALLAN WEBB, at the opening of the sixteenth session of the Calcutta Medical College. It is mainly occupied with "an examination into the state of medicine in India, previous to the introduction of European science, and with a comparison of it with medical science among the Greeks ; especially as respects —I. *Anatomy ;* II. *Physiology ;* III. *Pathology and Practical Medicine.*"

In Anatomy, the knowledge of the Hindoos was most limited, being only obtained by rubbing with a brush a body which had undergone putrefaction for seven days. Dr. Webb refers to the beautiful muscular expression and anatomical correctness of the Grecian sculptures ; and states that even "the most perfect specimens of Hindoo art—the relievos in their most ancient cavern temples, show nothing that for truth or form can compare with Greek specimens of art". These sculptures give no evidence that the Hindoos had ever attained to a knowledge of the muscles, or of their power of expression.

In Physiology, we have the "elementary theory" present, both in Hindoo and in Greek medicine. Hippocrates and Plato among the Greeks, and Charaka and Sushruta among the Hindoos, all agreed in teaching that fire, air, earth, and water, were the constituent elements of their human body ; and to these the Hindoos added *ether (akasa).* The following specimen of physiological doctrine is given by Dr. Webb, from the writings of Sushruta, the Galen of India. "'When digestion is accomplished, the respective elements unite with those which had entered into the formation of the body : the earth unites with earth, water with water, etc.; and they, acting on the inherent qualities of each of the five elements, mix and increase those in the body ; smell, the property of earth, with that of the body, taste with water, touch with air, and sound with ether.' This", says Dr. Webb, "is exactly what Empedocles taught—viz., that sensation takes place only through the affinity of elements composing the object perceived, with the elements of the perceptive organs or senses".

In the Hindoo system, air, bile, phlegm, and blood, are the chief humours of the body ; and these four words "as fully explain the mysteries of Hindoo pathology, as '*pax vobiscum*' represents in the mouth of Wamba, the son of Witless, all requisite learning, all monkish theology". Now these potent agents—air, bile, phlegm, and blood—are dealt out by Plato, just in the same style as by Charaka and Sushruta, as being, when deranged, the source of all diseases. And Dr. Webb brings forth very cogent internal evidence to prove the Hindoo origin of the Greek medical philosophy. "When we remember that Pythagoras introduced Brahminical institutions into Greece ; that he, as well as Plato, believed in the transmigration of souls ; that Hindoos never travelled, but Greeks did ; we can have very little doubt, that India was the source whence the Greeks derived their system of philosophy and of medicine. The analogy between the Hindoo and Greek systems of medicine is certainly much too close to be the result of accident": and this view is strengthened by the remarkable similarity in the writings of the philosophers of the two nations.

Such was the state of professional darkness among the Hindoos, until the institution of the Medical College in Calcutta in 1835; and, among the triumphs which are gradually being gained over prejudices, one of the most important has been the engaging the Mahomedan Hindustani students in the dissection of the human body. For this, the enlightened Hindoo practitioner will have to remember with gratitude the energy of Dr. Goodeve, and Pundit Moodoosudun Guptoo. "We must all rejoice", says Dr. Webb, "at the success of this great experiment, which has, in the vernacular tongue, brought within the grasp of the people that knowledge which is of all others the foundation of medical science. Now that the splendid work on Anatomy, which my colleague Dr. Mouat has completed, in the Oordoo language, is in the hands of these students, their difficulties are much less. It is, I apprehend, the first work upon the subject which has been compiled for Mahomedan students since the days of Galen."

Notwithstanding the miserable condition of the Hindoo pathology, it has been said that their practical medicine was in a better state. "In therapeutics, we hear of cures now-a-days of epilepsy and lepra, by combinations of drugs reputed to be of great antiquity. Professor Royle proves that Greeks and Arabs borrowed from their materia medica. In midwifery, we find that embryotomy was practised, and rules laid down for delivery. In surgery, lithotomy is described, operations for new ears and noses, for piles, fistula, cataract, etc." And Dr. Webb, who is a believer in mesmerism, mentions this practice as among the most curious relics of Hindoo medicine. The operation for cataract is fairly described by Sushruta, and was generally practised in India before the English arrived in that country. The itinerant *Baidias* sometimes poke out eyes; but Dr. Webb has seen many to whom they have restored sight. It is very probable also, that lithotomy was commonly practised at a period (A.D. 1460) when European surgery was in such a low state, that Colot, in Paris, was obliged to beg a man's life from the gallows to prove that the operation was not mortal!

Much good may be hoped for—and, indeed, we may say, has already resulted—from the establishment of the Calcutta Medical College, and from the diffusion of European science among the natives of India. We are glad to notice the following encouraging tidings of four young Hindoos, who were a few years since sent to England to pursue their medical studies in University College. "Dwarkanath Bose was the first of our gallant band of medical pioneers, to return to us with the diploma of the Royal College of Surgeons. He is now one of our teachers of anatomy. Soorjoo Coomar Chuckerbutty, just returned with the diploma of the London University, is Assistant-Physician to the College Hospital. Drs. Seal and Bose both hold appointments in this city."

Before concluding, we may record, in connection with the above subject, our satisfaction at observing that Persia, Abyssinia, and Hawaii, had last session furnished students to the Medical School of Paris. And, at the same time, we must express the disgust which we felt at reading that some students at a medical college in the land of liberty, equality, and fraternity—America—had sought, though ineffectually, to deprive some coloured persons of the privilege of attending lectures. We wish success to the Indian Medical Colleges, and to all attempts to diffuse sound knowledge, special or general, among the less civilised nations; and we would rejoice to hear that Drs. Quashi and Sambo had gone forth, enlightened with European knowledge, to practise the healing art among their brethren of Congo or Guinea, and to introduce to them the comforts and blessings of civilisation and Christianity.

We recommend Dr. Webb's Lecture to all, who are interested in the subject of which it treats.

A Letter to the Rt. Hon. Sir George Grey, Bart., M.P., on Medical Registration, and the Present Condition of the Medical Corporations. By Emeritus. pp. 22. London: 1851.

Of all the pamphlets that have appeared during the excitement attending the medical reform question, this is one of the best. It is evidently written by one who has no interested motives to bias his mind in favour of any of the present Corporations; and, indeed, from the fact, that he dates his pamphlet from the London Custom House, and from the title which he chooses for his *incognito*—Emeritus—it is evident that he no longer practises the medical profession. He does not, however, fall into the opposite error of pouring out indiscriminate abuse against all the licensing and examining bodies; but he very judiciously, as we think, points out the peculiar defects in the existing systems, and recommends plans for their amelioration. His chief object in this pamphlet appears to be, to recommend the establishment of an uniform system of registration of medical practitioners; a proposition so reasonable, that we cannot but wonder that it has never been adopted. The chief defect in previous plans of registration was, that the mere registration was to give almost a legal right to practise, and the effect would have been to confound all distinctions in the profession; a consummation which we certainly do not desire. But Emeritus recommends that all persons who register, should also append their qualifications; the effect of which plan would be, as we conceive, not to confound the grades of the profession, but distinctly to denote them: and the public would then no longer be excusable for sending for a licentiate of Apothecaries' Hall, possessing no other qualification, to set a broken leg or operate for a hernia; nor, on the other hand, would they send for a member of the Royal College of Surgeons of England, possessing only that qualification, for the treatment of pneumonia or hydrocephalus. In many of the views concerning the defects of existing systems, we heartily concur with the author of the pamphlet. We agree with him, that a pupilage of one or two years would be better than the present system of a compulsory apprenticeship of five years; that the diploma of medicine ought not to be given, as it is in the Scotch Universities, at the early age of twenty-one, and after a curriculum of education and an examination in no degree superior to those of the London Apothecaries' Company; and that the present system of granting diplomas by the London College of Surgeons is very defective, because, in the words of the author, "the limited examination of the Royal College of Surgeons, London", enables the members to obtain a sanction, "by which, without having passed any examination in many important branches of medical science, they impose upon the ignorance and credulity of the public in medical matters; and though imperfectly educated, and only half examined, they practise every branch of the profession, even in this country, but particularly in the colonies, and on board of emigrant ships, to which they should never be appointed on the strength of the diploma of the London College. If this had been attended to, the surgeons attached to those vessels would have been a more educated, and consequently superior class, and might have checked the disgraceful scenes reported to have lately occurred on board those ships. It also has the injurious tendency," adds the author, "of lowering the standard of medical education, and of causing many idle and ignorant medical students from Scotland and Ireland, to pass for surgeons the College of England, who are tempted, by the reduced scale of examination, to avoid the more extensive one of the Scotch and Irish Colleges; and it is even said," (but here we hope our author is in error,) "that their rejected candidates have subsequently passed, and found almost immediate admission into, the London College."

We conclude by repeating our good opinion of this pamphlet; and although, from its bold and independent tone, it is not likely to obtain favour from any of the Corporations, we think that, on that very ground, it

ought to attract the attention of Government. The plan of registration is so simple, and its advantages so great, that we wonder it is not adopted without delay.

Das Schraeg Verengte Becken nebst einem Anhange ueber die wichtigsten Fehler des weiblichen Beckens ueberhaupt. Von Dr. Franz Carl Naegele. Mit sechzehn Tafeln. Zweite Ausgabe. Mainz: 1850.

[The Obliquely Contracted Pelvis, with an Appendix on the most important Defects of the Female Pelvis generally. By Dr. Franz Carl Naegele. With sixteen Engravings. Second Edition. pp. 118. Mayence.]

Dr. Naegele informs us, in his Introduction, that, so long as thirty-four years ago, he observed the first two specimens of the peculiar variety of pelvic deformity, which forms the subject of his present work. He was then struck with the difference which existed between this deformity, and that which results from rachitis and mollities ossium, and was led to regard the disease as one of a peculiar and undescribed kind; but it was not until the year 1828, that he succeeded in meeting with a pelvis, in his own practice, which presented the same deformity as the two which had previously engaged his attention. Since that time, he has caused investigations to be made, both by himself, and by his friends and pupils, in search of similar deviations from the natural structure; and these researches have been rewarded by the discovery of various similar cases of malformation of the female pelvis.

The distinguishing characters of this deformity are, complete anchylosis of one sacro-iliac symphysis, or complete union of the sacrum with one ilium; a wasting or defective formation of the lateral half of the sacrum, and diminished breadth of the anterior sacral foramina of the side where the anchylosis exists; on the same side, a diminished breadth of the os innominatum, and a diminished size of the ischiatic notch; and, in addition to these peculiarities, the sacrum appears to be pushed in towards the side of the anchylosis, and its anterior surface, on this side, is also more or less shortened, while the pelvic symphysis is pushed over to the opposite side, and thus this symphysis stands not on a level with the promontory, but obliquely opposite to it; and, on the side of the anchylosis, the interior surface of the lateral wall, and of the lateral half of the anterior wall of the pelvis, is less hollowed, or flatter, than in the normal pelvis.

Such is a brief description of this very interesting deformity, for the elucidation of which the profession is much indebted to Dr. Naegele. His work is illustrated by sixteen very beautiful engravings, most of them coloured; and, altogether, the work will add to the reputation of the late distinguished professor. In conclusion, we must add that several preparations similar to those described by Dr. Naegele exist in the museums of this country.

De Acidi Osmici in Homines et Animalia Effectu Commentatio Physiologica. Scripsit Prof. Dr. F. Branell, Vimariensis. pp. 117. Casani: 1849.

This is a dissertation upon the physiological effects of a substance hitherto very little known in its relations to the animal system. Professor Clausius, while examining the residue of the platinum ores, was struck by the singular properties of the vapours of osmic acid, as exhibited upon his assistant and his servants; and hence Dr. Branell was led to investigate more closely the powers of this acid. He therefore instituted a series of experiments on various animals, which occupied him for four years, and the results of his investigations are contained in the present treatise. The author deserves great credit for his industry in conducting this extensive series of experiments; and his treatise is a very good specimen of a toxicological monograph.

ALPHABETICAL CATALOGUE

Of the Papers which have appeared in the French Medical Journals for 1850.

BY ALEXANDER HENRY, M.D.

(Concluded from p. 366 of last Number.)

THE following are the Journals referred to in this Catalogue, with the abbreviations used.

Bulletin de l'Académie Nationale de Médecine ...	Bull. de l'Acad. de Méd.
Comptes Rendus de l'Académie des Sciences ...	Compt. Rend.
Archives Générales de Médecine	Arch. Gén. de Méd.
Bulletin Général de Thérapeutique	Bull. Gén. de Thér.
Gazette Médicale	Gaz. Méd.
——— des Hôpitaux	Gaz. des Hôp.
L'Union Médicale	Union Méd.
Annales d'Oculistique	Ann. d'Ocul.
——— Médico-Psychologiques	Ann. Méd.-Psych.
——— d'Hygiène Publique	Ann. d'Hyg. Pub.

LACHRYMAL Gland and Ducts, Congenital Hypertrophy of. GLUGE (Dr.) Ann. d'Ocul., April 1850, vol. v, 4th S., p. 155.

LACTATION, Remarks on. TROUSSEAU (M.) Gaz. des Hôp., Feb. 21 and 23, 1850, vol. ii, 3rd S., pp. 89 and 94.

LARYNGITIS, Œdematous, Bronchotomy in. SESTIER (Dr. F.) Arch. Gén. de Méd., August 1850, vol. xxiii, 4th S., p. 385 ; Sept., Nov., and Dec., vol. xxiv, pp. 35, 297, and 441.

LEAD-COLIC, Treatment of by Local and Internal use of Chloroform. ARAN (Dr.) Bull. Gén. de Thér., 1850, vol. xxxix, p. 296. Abs. in Lond. Journ. of Med., Jan. 1851, vol. iii, p. 67.

LITHOTOMY, bilateral. CAZENAVE (M.) Bull. de l'Acad. de Méd., Aug. 13, 1850, vol. xv, p. 1049. Lithotomy and Lithotrity, Accidents Complicating, and means of preventing them. PETRÉQUIN (M.) Gaz. Méd., July 20, Aug. 3 and 31, pp. 546, 578, 638.

LIVER, Description and Semeiological Value of some Symptoms of Disease of. MONNERET (M.) Bull. de l'Acad. de Méd., Oct. 15, 1850, vol. xvi, p. 71. Purulent Cyst communicating with Left Lobe of : Case. VAUTHIER (Dr. A.) Union Méd., Feb. 8, 1850, vol. iv, p. 58. Opening of Abscesses and suppurating Acephalocystic Tumour of into the Bronchi. FAUCONNEAU-DUFRESNE (M.) *Ibid.*, Oct. 15 and 17, 1850, vol. iv, pp. 502 and 506.

LUNG, diffuse Gangrene of. HARDY (M.) Gaz. des Hôp., March 19, 1850, vol. ii, 3rd S., p. 133.

LUPUS, Chloride of Gold in. MALICHECQ (Dr.) Bull. Gén. de Thér., 1850, vol. xxxviii, p. 456.

LYPOMANIA, Medico-legal Report of Case of. GIRARD (M. H.) Ann. Méd.-Psych., Jan. 1850, vol. ii, p. 55.

MAMMARY GLAND, Partial Hypertrophy of. LEBERT (M.) Gaz. des Hôp., Aug. 27 and 29, 1850, vol. ii, 3rd S, pp. 402 and 406.

MANUFACTURING TOWNS. VILLERME (M.) Ann. d'Hyg. Pub., April 1850, vol. xliii, p. 241.

MARITIME Diseases. DUTROULAU (M.) Gaz. Méd., Aug. 17, Sept. 14, vol. v, 3rd S., pp. 607, 670.

MEASLES without Eruption, in Paris. Gaz. Méd., April 20, 1850, vol. v, 3rd S., p. 295. Abs. in Lond. Journ. of Med., June 1850, vol. ii, p. 572.

MEDICAL CONSTITUTION of the Third and Fourth Quarters of 1849. Gaz. Méd., Feb. 9 and 16, 1850, vol. v, 3rd S., pp. 101 and 121. Of the First Quarter of 1850, in Paris : with especial regard to Meteorological Observations. Gaz. Méd., May 18 and 25, 1850, vol. v, 3rd S., pp. 370 and 390. Of the Second Quarter of 1850. Gaz. Méd., Aug. 17 and 31, 1850,

vol. v, 3rd S., pp. 605 and 630. Of the Third Quarter of 1850. Gaz. Méd., Nov. 30 and Dec. 7, 1850, vol. v, 3rd S., pp. 848 and 869.

Medical Report of the Asylum at Maréville. Morel (M.) Ann. Méd.-Psych., July 1850, vol. ii, p. 353.

Medicinal Treatment, absolute necessity of. Dorvault (M.) Bull. Gén. de Thér., 1850, vol. xxxviii, p. 27.

Menstruation, Influence of different forms of Genital Organs on. Bernard (Dr.) Union Méd., Oct. 22, 1850, vol. iv, p. 513.

Mental Diseases, Lectures on. Falret (M.) Gaz. des Hôp., May 21 and 23, June 20, July 2, 11, 23, 30, and 31, August 8 and 24, Sept. 5, 12, 17, and 28, Oct. 8, 22, and 31, Nov. 14 and 28, Dec. 14, 1850, vol. ii, 3rd S., pp. 238, 242, 290, 310, 326, 345, 358, 362, 373, 397, 417, 430, 437, 468, 474, 498, 513, 533, 559, 586.

Mercurial Poisoning (Hydrargyria) in Children. Baron (Dr. C.) Gaz. Méd., Jan. 12 and 26, 1850, vol. v. 3rd S., pp. 25 and 71.

Mercury, new method of Pulverising. Stanislas Martin (M.) Bull. Gén. de Thér., 1850, vol. xxxix, p. 499.

Mineral Waters of Cransac, Report on. Caventou (M.) Bull. de l'Acad. de Méd., 1850, vol. xv, p. 506. Of Montégut-Ségla (Haute-Garrone). Henry (M. O.) *Ibid.*, July 9, p. 941. Of Château Gontier. Henry (M. O.) *Ibid.*, July 9, p. 944. Ferruginous, of Bagnères de Bigorre. Henry (M. O.) *Ibid.*, July 23, p. 980. Of Bagnères de Luchon. Filhol (M.) *Ibid.*, Aug. 13, p. 1035. Of Wattevilliers. Henry (M. O.) *Ibid.*, Oct. 29, vol. xvi, p. 84. Of Dames Brosson at Casset. *Ibid.*, p. 86.

Monomania, Intellectual, case of. Girard (M. H.) Ann. Méd.-Psych., July 1850, vol. ii, p. 413.

Murmur, Placental, new Theory of Cause of. Cazeaux (Dr. P.) Arch. Gén. de Méd., March 1850, vol. xxii, 4th S., p. 336. Abs. in Lond. Journ. of Med., June 1850, vol. iii, p. 576.

Muscular Current, Law of: modification produced by Contraction. Du Bois Raymond (M. E.) Compt. Rend., March 18, and April 8, 1850, vol. xxx, pp. 349 and 406.

Mydriasis, Different kinds of. Tavignot (M.) Gaz. des Hôp., March 12, 1850, vol. ii, 3rd S., p. 123.

Myelitis, Lectures on. Gendrin (M.) *Ibid.*, March 30, April 4 and 13, 1850, vol. ii, 3rd S., pp. 155, 161, and 177.

Needle-Makers, Health of. Gaultier de Claubry (M.) Ann. d'Hyg. Pub., Jan. 1850, vol. xliii, p. 82.

Nervous Influence, Rapidity of Transmission of. Helmholtz (Dr.) Compt. Rend., Feb. 25, 1850, vol. xxx, p. 204.

Neuralgia (and Muscular Rheumatism), Hydrotherapeutic Treatment of. Fleury (Dr. L.) Gaz. Méd., April 13, 20, and May 4, 1850, vol. v, 3rd S., pp. 283, 300, and 342. Of Brachial Plexus. Neucourt (Dr. F.) Arch. Gén. de Méd., Nov. 1850, vol. xxiv, 4th S., p. 257. Epidemic ophthalmic, in Algiers. Bertherand (Dr. E. L.) Ann. d'Ocul., Nov. 1850, vol. vi, 4th S., p. 223. Neuralgic affections, nature of. Chomel (M.) Union Méd., Jan. 24, 1850, vol. iv, p. 41.

Nose, case of Hypertrophy of. Hutin (M.) Bull. de l'Acad. de Méd., 1850, vol. xv, p. 582.

Ophthalmia in the Portuguese Army. Cunier (Dr. F.) Ann. d'Ocul., Jan. and Feb. 1850, vol. v, 4th S., p. 52. Among the poor in Brussels. Bosch (Dr. J.) *Ibid.*, July, Aug. and Sept. 1850, vol. vi, 4th S., p. 95. Purulent and Gonorrhœal, Differential Diagnosis of. Henrotay (Dr. E.) *Ibid.*, Oct. 1850, vol. vi, 4th S., p. 179. Contagious, in new-born children, identical with Army Ophthalmia. Thiry (Dr.) *Ibid.*, May and June, 1850, vol. v, 4th S., p. 225. Chronic, cauterisation of nasal fossæ in. Tavignot (M.) *Ibid.*, p. 232. Treatment of. Langenbeck

(M. Max.) *Ibid.*, July, Aug. and Sept. 1850, vol. vi, 4th S., p. 100. Granular, acetate of lead in. CUNIER (Dr.) Union Méd., Feb. 12, 1850, vol. iv, p. 75. BUYS (Dr.) Ann. d'Ocul., July, Aug. and Sept. 1850, vol. vi, 4th S., p. 114. See Lond. Journ. of Med., Feb. 1850, vol. ii, p. 109. VAN LIL (Dr.) *Ibid.*, Nov. 1850, p. 217.

OPHTHALMIC DISEASES, Collodion in. DEVAL (Dr. Charles). Union Méd., April 4 and 6, 1850, vol. iv, pp. 165 and 170.

OPIUM and its Preparations, Pharmacological Remarks on. CHEVALIER and GUILLIERMOND (MM.) Bull. Gén. de Thér., 1850, vol. xxxviii, p. 118.

ORBIT, numerous pieces of Glass introduced into. COLLETTE (Dr. F. C.) Ann. d'Ocul., May and June 1850, vol. v, 4th S., p. 217.

ORCHITIS; treatment by Chloroform. BOUISSON (M.) Union Méd., Jan. 8, 1850, vol. iv, p. 16. From Annales de la Soc. Méd. de la Flandre.

OVARIES, influence of, ancient opinions on. CHEREAU (Dr. A.) Union Méd., Nov. 9, 1850, vol. iv, p. 543.

OVUM of seven or eight weeks, with Decidua entire. CAZENAVE (M.) Bull. de l'Acad. de Méd., 1850, vol. xv, p. 546.

OXYGEN, Function of in the Animal Economy. MIALHE (M.) *Ibid.*, Sept. 17, 1850, vol. xv, p. 1124.

OZÆNA and its Treatment. SIMON (M. Max.) Bull. Gén. de Thér., 1850, vol. xxxix, p. 9.

PALPEBRAL GRANULATIONS, Pathological Anatomy of. HAIRION (M.) Gaz. Méd., May 4, 1850, vol. v, 3rd S., p. 336; and Ann. d'Ocul., March 1850, vol. v, 4th S., p. 109. Various modes of treating. DE CONDÉ (Dr.) Ann. d'Ocul., Nov. 1850, vol. vi, 4th S., p. 205. (See also, Ophthalmia.)

PALUDAL DISEASES. DUCHASSAING (M.) Gaz. Méd., Sept. 21 and Oct. 12, 1850, vol. v, 3rd S., pp. 684, 743.

PANCREATIC JUICE, use of, in Digestion. BERNARD (M.) Gaz. Méd., March 23, 1850, vol. v, 3rd S., p. 216.

PARACENTESIS THORACIS in Hôpital des Enfans Malades. LACAZE DE THIERS (M.) Union Méd., March 21, 23, 26, 30, and April 2, 1850, vol. iv, pp. 142, 145, 149, 158, and 161.

PARALYSIS, General, of the Insane. MOREAU (Dr. J.) Gaz. Méd., May 11, 1850, vol. v, 3rd S., p. 356. BILLOD (Dr. E.) Ann. Méd.-Psych., Oct. 1850, vol. ii, p. 608. General Diagnosis of various forms of, by Local Galvanism. BRIERRE DE BOISMONT (M.) Union Méd., August 26, 1850, vol. iv, p. 418. Facial. *Ibid.*, Jan. 12 and 15, 1850, vol. iv, pp. 21 and 25. Facial, remarkable case of. CRUVEILHIER (M.) Gaz. des Hôp., Feb. 14, 1850, vol. ii, 3rd S., p. 77. Facial, exaltation of Hearing in. LANDOUZY (M. H.) Union Méd., Dec. 21 and 26, 1850, vol. iv, pp. 616 and 623. Of third and sixth nerves, observations on. DEVAL (M. C.) Ann. d'Ocul., April 1850, vol. v, 4th S., p. 147. Of Upper Extremity, on state of Electro-muscular Contractility and Sensibility in. DUCHENNE (Dr.) Arch. Gén. de Méd., Jan. 1850, vol. xxii, 4th S., p. 5.

PARASITIC animals, entozoic, theory of origin of. LÉVEILLÉ (Dr.) Union Méd., March 30, 1850, vol. iv, p. 157.

PARIS, Statistics of Deaths in, since 1809. TRÉBUCHET (M.) Ann. d'Hyg. Pub., vol. xliii, Jan. 1850, p. 5; vol. xliv, July, p. 71; Oct., p. 322.

PAROTITIS, epidemic of, in Geneva, during 1848 and 1849. RILLIET (Dr.) Gaz. Méd., Jan. 12 and 19, 1850, vol. v, 3rd S., pp. 22, 42.

PATHOLOGICAL ANATOMY, plan and direction to be followed in study of. SEGOND (Dr. L. A.) *Ibid.*, Jan. 26, vol. v, 3rd S., p. 69.

PELLAGRA in the Valley of Vernet (Eastern Pyrenees); cases, nature, and causes. COURTY (M. A.) Gaz. Méd., July 13, Aug. 10 and 24, 1850, vol. v, 3rd S., pp. 522, 592, and 620. Case of, followed by death. Un. Méd., August 22, 1850, vol. iv, p. 409.

Pemphigus, Clinical Lecture on. Cazenave (M.) Gaz. des Hôp., Oct. 24, 1850, vol. ii, 3rd S., p. 501.

Peritonitis from Injection of Uterus. Gubian (M.) Gaz. des Hôp., March 30, 1850, vol. ii, 3rd S., p. 155. Chronic, Clinical Researches on. Bernard (M. Ch.) *Ibid.*, Jan. 5, 10, and 12, 1850, vol. ii, 3rd S., pp. 9, 17, 22.

Phlebitis, Spontaneous, Treatment of. Forget (M.) Bull. Gén. de Thér., 1850, vol. xxxviii, p. 337.

Phosphene as a sign of Functional Life in the Retina. Serre (M.) Ann. d'Ocul., July, Aug. and Sept. 1850, vol. vi, 4th S., p. 31 ; Oct. p. 160. In Myopia and Presbyopia. Serre (M.) Bull. Gén. de Thér., 1850, vol. xxxix, p. 410. In Amaurosis. *Ibid.*, p. 454.

Phthisis, Pulmonary, Cl. Lect. on. Gendrin (M.) Gaz. des Hôp., Jan. 29, Feb. 5, 12, 19, 28, and March 14, 1850, vol. ii, 3rd S., pp. 49, 61, 73, 86, 101, and 125. Phthisis and Pregnancy, reciprocal influence of. Grisolle (M.) Arch. Gén. de Méd., Jan. 1850, vol. xxii, 4th S., p. 41. Tr. in London Journ. of Med., April 1850, vol. ii, p. 382. Cod-liver oil in. Duclos (Dr.) Bull. Gén. de Thér., 1850, vol. xxxviii, pp. 391 and 488. Seeds of Phellandrium Aquaticum in. Valleix (M.) *Ibid.*, 1850, vol. xxxviii, pp. 106 and 153. Sandras (Dr.) *Ibid.*, 1850, vol. xxxviii, p. 241. Inhalation of Carbonic Acid gas in ; new Auscultatory Sign of Latent Tubercles. Goin (Dr.) Bull. de l'Acad. de Méd., Oct. 15, 1850, vol. xvi, p. 56.

Physiology, History and General Systemisation of. Legond (Dr. L. A.) Gaz. Méd., June 22, and July 6, 1850, vol. v, 3rd S., pp. 464 and 504.

Pityriasis capitis, Cl. Lect. on. Cazenave (M.) Gaz. des Hôp., Sept. 10, 1850, vol. ii, 3rd S., p. 426.

Pleural Effusions, Production of Metallic Sound in Course of. Notta (Dr. A.) Arch. Gén. de Méd., April 1850, vol. xxii, 4th S., p. 423.

Pleurisy, Secondary, following Inflammation of the Breast or Axilla. Broca (Dr. P.) *Ibid.*, April 1850, vol. xxii, 4th S., p. 385. Chronic, Paracentesis Thoracis in. Laveran and Boudant (MM.) Bull. de l'Acad. de Méd., 1850, vol. xv, p, 298.

Pneumonia, Importance of Rigor in Diagnosis of. Chomel (M.) Union Méd., Feb. 19, 1850, vol. iv, p. 87. Paralysis following. Macario (Dr.) Bull. Gén. de Thér., 1850, vol. xxxix, p. 543. Abs. in Lond. Journ. of Med., Feb. 1851, vol. iii, p. 163. Of New-born Children, certain Stethoscopic Signs in Relation to. Trousseau and Lasegue (Drs.) Arch. Gén. de Méd., Oct. 1850, vol. xxiv, 4th S., p. 129.

Population, Statistical Researches on Laws of. Boudin (M.) Ann. d'Hyg. Pub., July 1850, vol. xliv, p. 5.

Portal Vein, Inflammation of, Case. Marotte (M.) Gaz. des Hôp., April 9, 1850, vol. ii, 3rd S., p. 170.

Potash, Oxalate of, Poisoning by, in mistake for Sulphate of Potash. Union Méd., March 14, 1850, vol. iv, p. 131.

Potassium, Bromide of, Physiological Effects of : Production of Anæsthesia. Rames (M. J.) Union Méd., Jan. 5, 1850, vol. iv, p. 10. Huette (M.) Gaz. Méd., June 8, 1850, vol. v, 3rd S., p. 432.

Pregnancy, Diagnosis of. Dubois (M. P.) Gaz. des Hôp., April 4 and 18, 1850, vol. ii, 3rd S., pp. 161 and 185.

Pupil, Glistening of. Blasius (Dr.) Ann. d'Ocul., Jan. and Feb., 1850, vol. v, 4th S., p. 3.

Pus, Blue, Nature and Causes of. Sédillot (M.) Gaz. Méd., Sept. 7, 1850, vol. v, 3rd S., p. 656.

Pustule, Malignant, Internal Pathological Lesions in. Boyer (M.) Gaz. des Hôp., Oct. 15, 1850, vol. ii, 3rd S., p. 485.

Quinine, Sulphate of, Mode of Action, and General Therapeutic Properties of. Semanas (Dr.) Gaz. Méd., Jan. 19, 1850, vol. v, 3rd S., p. 47.

Rectocele, Vaginal: Cases. Malgaigne (M.) and Forget (M. A.) Union Méd., May 21, 1850, vol. iv, p. 245.

Rectum, Tumour of, containing Débris of a Fœtus. Bouchacourt (M.) Gaz. Méd., Aug. 31, 1850, vol. v, 3rd S., p. 635. Stricture of, Treated by Forced Dilatation. Dieulafoi (M.) Union Méd., Dec. 31, 1850, vol. iv, p. 631. Case of Absence of, with apparently well-formed Anus. Forget (Dr. A.) *Ibid.*, August 29, 1850, vol. iv, p. 422.

Rheumatism, Acute and Chronic Articular; Lect. on. Gendrin (M.) Gaz. des Hôp., June 6, 22, 29, July 6 and 11, 1850, vol. ii, 3rd S., pp. 265, 295, 306, 319, and 327. Acute Articular, terminating in Suppuration. Trousseau and Lasègue (MM.) Union Méd., August 24, 1850, vol. iv, p. 413. Acute Articular, Observations on Treatment of. Legroux (M.) Bull. Gén. de Thér., 1850, vol. xxxix, p. 145. Acute Articular, Treatment by Flying Blisters. Dechilly (Dr.) Bull. de l'Acad. de Méd., April 30, 1850, vol. xv, p. 665. Martin-Solon (M.) Bull. Gén. de Thér., 1850, vol. xxxviii, pp. 385 and 534. Muscular, (and Neuralgia), Cold Douche and Sweating in. Fleury (M.) Compt. Rend., Jan. 21, 1850, vol. xxx, p. 51.

Rice-Fields, Insalubrity of. Boileau-Castelnau (Dr. Ph.) Ann. d'Hyg. Pub., April 1850, vol. xliii, p. 327.

Rickets and Osteomalacia, Comparison of. Trousseau and Lasègue (MM.) Union Méd., June 27, July 4, 20, 30, August 8, Oct. 12, 22, 31, Nov. 7, 1850, vol. iv, pp. 314, 326, 354, 370, 385, 497, 514, 530, and 537.

Rupia, Cl. Lect. on. Cazenave (M.) Gaz. des Hôp., Nov. 16, 1850, vol. ii, 3rd S., p. 538.

Salicaria, Chemical and Medical Researches on. Meurdefroy and S. Martin (MM.) Bull. Gén. de Thér., 1850, vol. xxxviii, pp. 66 and 121.

Scarlatina, Abscess in Neck after, and Rupture of Internal Jugular Vein: Recovery. Depéret-Muret and Boulland (Drs.) Union Méd., August 24, 1850, vol. iv, p. 414. Abs. in Lond. Journ. of Med., April 1851, vol. iii, p. 373.

Sciatica, Observations on Treatment of. Forget (Dr.) Bull. Gén. de Thér., 1850, vol. xxxix, p. 337. Treatment of by Cauterisation of the Helix. Duchenne (Dr.) Union Méd., Oct. 8, 1850, vol, iv, p. 489. Valleix (M.) *Ibid.*, Nov. 21 and 23, vol. iv, pp. 564 and 568. Treatment of, by Cutaneous Galvanism. Duchenne (Dr.) *Ib.*, Oct. 24, 1850, vol. iv, p. 517.

Scrofula, Treatment of, by Walnut-Leaves. Negrier (Dr.) Arch. Gén. de Méd., Feb. and April 1850, vol. xxii, 3rd S., pp. 173 and 447.

Scurvy. Dutroulau (M.) Gaz. Méd., Sept. 17, 1850, vol. v, 3rd S., p. 670.

Seminal Matter, Peculiar Alteration in. Demeaux (M.) Gaz. des Hôp., Oct. 17, 1850, vol. ii, 3rd S., p. 489.

Shoulder-Presentations, Amputation of Arm not always necessary in. Chailly-Honoré (M.) Bull. Gén. de Thér., 1850, vol. xxxix, p. 25. Abs. in Lond. Journ. of Méd., Jan. 1851, vol. iii, p. 73.

Skin-Diseases, Cauterisation in. Cazenave (M.) Gaz. des Hôp., Sept. 24, 1850, vol. ii, 3rd S., p. 449.

Speculum Uteri, New Form of, for Examining the whole extent of the Vagina and Cervix Uteri. Magonty (Dr.) Union Méd., Oct. 29, 1850, vol. iv, p. 525.

Spermatic Ducts, New Form of Obliteration of. Gosselin (M.) Gaz. Méd., Oct. 12, 1850, vol. v, 3rd S., p. 756.

Spinal Cord, Preservation of Life after Removal of Large Portion of. Brown-Séquard (Dr.) Compt. Rend., June 24, 1850, vol. xxx, p. 828.

Spleen, Hypertrophy of: Cases. Grisolle (M.) Bull. de l'Acad. de Méd., May 28, 1850, vol. xv, p. 762. Marchal de Calvi (M.) *Ibid.*, June 4, p. 797.

Staphyloma, Sclero-choroidal; with Microscopic Observations on Staphyloma in general. Hairion (Dr. F.) Ann. d'Ocul., July, Aug., and Sept., 1850, vol. vi, 4th S., p. 60.

Staphyloraphy, Operation for: Cases. Sédillot (M.) Compt. Rend., March 18 and April 1, 1850, vol. xxx, pp. 310 and 374; Aug. 5, vol. xxxi, p. 166. Memoir on. Roux (M.) *Ibid.*, June xxx, vol. 24, p. 789.

Strabismus, New Classification of. Corvisart (Dr. L.) Gaz. des Hôp., Jan. 10, 1850, vol. ii, 3rd S., p. 19. Direct. Borelli (Dr. J. B.) Ann. d'Ocul., July, Aug., and Sept., 1850, vol. vi, 4th S., p. 90; and Gaz. Méd., Sept. 21, 1850, vol. v, 3rd S., p. 690. Corvisart (Dr. L.) Gaz. des Hôp., Jan. 19, 1850, vol. ii, 3rd S., p. 35.

Strangulation, Internal, from Pressure of Cancerous Tumour: Case. Union Méd., Jan. 8, 1850, vol. iv, p. 15.

Sugar, Origin of, in the Animal Economy. Bernard (M. C.) Gaz. Méd., April 6, 1850, vol. v, 3rd S., p. 256.

Suicide during Insanity, Statistical Researches on. Brierre de Boismont (M.) Ann. d'Hyg. Pub., Jan. 1850, vol. xliii, p. 144.

Synchysis, Glistening: Extraction and Examination of Brilliant Plates in Anterior Chamber of Eye. Sichel (Dr.) Ann. d'Ocul., July, Aug., and Sept., 1850, vol. vi, 4th S., p. 491; Oct., p. 145.

Synovial Cysts of Hand and Thumb. Gosselin (M.) Bull. de l'Acad. de Méd., June 18, 1850, vol. xv, p. 868.

Syphilide, Squamous. Cazenave (M.) Gaz. des Hôp., Oct. 1, 1850, vol. ii, 3rd S., p. 461. Papular, *Ibid.*, Oct. 10, p. 477.

Syphilis, Letters on. Ricord (M.) Union Méd., Jan. 22, 31, Feb. 16, 26, March 19, 28, April 9, 23, May 28, June 6, 13, 20, July 2, 16, 23, 30, August 13, 26, Sept. 10, Oct. 1, 15, Nov. 2, 26, Dec. 3, 1850; vol. iv, pp. 37, 54, 81, 98, 137, 153, 173, 197, 257, 273, 285, 301, 321, 345, 357, 369, 393, 417, 441, 477, 501, 533, 571, 583. Inoculation of Animals with. De Welz (Dr. R.) Gaz. Méd. July 20, 1850, vol. v, 3rd S., p. 544. Auzias-Turenne (Dr.) Union Méd., August 6, 1850, vol. iv, p. 381. Transmission of from New-born Children to Nurses. Bouchut (E.) Gaz. Méd., April 20, 1850, vol. v, 3rd S., p. 296. Transmission of from Parent to Child, etc. Cazenave (M.) Gaz. de Hôp., Aug. 27, 1850, vol. ii, 3rd S. p. 401. A possible cause of the Death of a Fœtus. Dubois (M. Paul). Gaz. Méd, May 25, 1850, vol. v, 3rd S., p. 392. Constitutional Pains which may coexist with. Diday (M.(*Ibid.*, Nov. 9, 16, 30, and Dec. 7, 1850, vol. v, 3rd S., pp. 806, 820, 856, and 876.

Syphilitic Muscular Retraction. Notta (Dr. A.) Arch. Gén. de Méd., Dec. 1850, vol. xxiv, 4th S., p. 413. Ulcers, Secondary, treated by Diachylon Plaster. Dumas (M. A.) Bull. Gén. de Thér., 1850. vol. xxxix, p. 503.

Tænia, Nervous Symptoms produced by. Legendre (Dr. F. L.) Arch. Gén. de Méd., June 1850, vol. xxiii, 4th S., p. 189. Abs. in Lond. Journ. of Med., Nov. 1850, vol. ii, p. 1073. Kousso and Oil of Male Fern in. Martin-Solon (M.) Bull. Gén. de Thér., 1850, vol. xxxviii, p. 299. Abs. in Lond. Journ. of Med., Dec. 1850, vol. ii, p. 1182.

Tannin in Eye-Diseases. Cambrelin (Dr. J.) Ann. d'Ocul., July, Aug. and Sept. 1850, vol. vi, 4th S., p. 118. Hairion (Dr. F.) *Ibid.*, p. 119. Cunier (Dr. F.) p. 121.

Tartar-emetic in very small doses, in certain Thoracic Affections. Bernardean (Dr. E.) Bull. Gén. de Thér., 1850, vol. xxxviii, p. 311.

Tetanus, Idiopathic, cured by Chloroform. Barth (Dr.) Bull. Gén. de Thér., 1850, vol. xxxix, p. 364. Traumatic, Belladonna in. Vial (M.) *Ibid.*, 1850, vol. xxxviii, p. 62. Traumatic, cured by Inhalation of Chloroform. Boraud (Dr. A.) *Ibid.*, 1850, vol. xxxix, p. 126.

Transposition of Heart and Lungs in a Child. Boyer (M. L.) Bull. de l'Acad. de Méd., 1850, vol. xv, p. 589.

Trees, Plantation of, in Towns. Jeannel (Dr.) Ann. d'Hyg. Pub., Jan. 1850, vol. xliii, p. 49.

Tuberculisation, Etiology of. Vanner (Dr.) Bull. de l'Acad. de Méd., Oct. 15, 1850, vol. xvi, p. 68.

Tuberculous Glands in Neck, case of Extirpation of. Coste (M.) Union Méd., August 10, 1850, vol. iv, p. 390.

CRITICAL DIGEST OF THE BRITISH AND FOREIGN MEDICAL JOURNALS.

PRACTICE OF MEDICINE AND PATHOLOGY.

HEMLOCK POULTICES AND CALOMEL IN THE ASCITES OF CHILDREN.

In 1849, M. Trousseau tapped four children for Ascites: they all died. From this and similar considerations, he has been led to adopt and recommend calomel in small doses, followed by the application of hemlock poultices to the abdomen.

The calomel is given to the amount of 2½ *centigrammes* (rather less than half a grain) daily, divided into six doses. At the end of six days, at the farthest, salivation takes place; there is also occasionally diarrhœa. The calomel is now discontinued, and hemlock cataplasms are kept constantly applied to the abdomen. These are prepared by rubbing up two spoonfuls of powder of hemlock in some thick linseed-water, which is then spread over a linseed-meal poultice. This is as efficacious as the pure hemlock cataplasm, which is prepared with 200 *grammes* (nearly 6½ ounces) of hemlock powder in a sufficient quantity of hot water. M. Trousseau has long recommended its application to the chest in phthisis.

Under the successive influence of the calomel and the hemlock poultices, the abdominal effusions are absorbed, even under the most unfavourable circumstances. And we may here call attention to a principle which M. Trousseau has derived, we believe, from M. Recamier, and which he never ceases to repeat in his clinical lectures; that, in the treatment of apparently incurable diseases, we should take our stand on a favourable diagnosis, and not assume an irrevocably fatal termination. Pathological anatomy has shewn us the true relations of many diseases supposed to be essential; but it has led us also into an opposite extreme. Hence dropsy always suggests the idea of an incurable organic disease; hæmoptysis that of pulmonary tubercle. Sufficient attention is not paid to the *experientia fallax* of which Hippocrates speaks, and which is specially applicable to diagnosis. All cases of sub-acute peritonitis are not tubercular; there are rheumatic cases —rare, it is true, in adults, but more common in children.

The calomel and the hemlock cataplasms have an absorbent and resolvent effect, even in ascites connected with organic lesion. There was lately a little girl in M. Trousseau's wards, who had had ascites for three months. Nothing abnormal was observed in the heart or liver; but there was reason to suspect the existence of mesenteric tubercles. M. Trousseau prescribed calomel. Salivation took place on the eighth day, and he then applied the hemlock poultices. After fifteen days of this treatment, the fluid was absorbed; and there was felt, in the left flank, a nodulated irregular tumour, of the size of a pigeon's egg, and probably tubercular. The treatment was of no avail against this affection; but it removed the complication, and this is a great step. [*Journal des Connaissances Médico-Chirurg.*, 16 March, 1851.]

MISTAKEN SEX FROM CLOSURE OF THE VAGINA, AND HYPERTROPHY OF THE CLITORIS.

In September, 1850, Dr. Haskins, of Richmond City, U.S., examined, by request, a slave belonging to a gentleman in Mecklenburg County, Virginia, who had been reported as "A Curious Case of Hermaphrodism", by Dr. S. H. Harris, in a communication made to the twenty-seventh number of the *American Journal of Medical Sciences.*

The following is an abridgment of Dr. Haskins' paper as published in the *Stethoscope*:—

I must say, in justice to Dr. Harris, that the examination which I was enabled to make was much more satisfactory than the one from which he made the report. His having been made at a time when he did not expect it, he was unprepared with instruments to assist him, and had also to contend with the reluctance which is usually manifested by such persons to have their real situation known.

Her appearance is that of a woman dressed in man's apparel. Her stature is low, frame delicate, hips broad, lower extremities bent or inclined inwards at the knee-joints, making her *knock-kneed*, gait shuffling, instead of the firm, strong, elastic step of manhood, the face is perfectly smooth, exhibiting no trace of beard, although she is now twenty-one years old. The mammæ although not exhibiting the plumpness of virginity, are as well developed as you ordinarily see them. The *mons veneris* is prominent and well developed, being covered with hair as in the female, and immediately over the symphysis pubis in situated an organ which resembles almost exactly a dwarfish penis. It is about an inch long, and half an inch in diameter, terminated by a tubercle corresponding in shape and appearance with the *glans penis*. There also appears to be the orifice of an urethral canal, properly located in the glans, but upon closer examination it proves to be the terminus of a fissure situated on the inferior surface of the organ, formed by the approximation of the edges of what appears to be the nymphæ, which had adhered to, and were stretched over it, so as partly to contribute to the formation of a preputial covering. The prepuce consisted of that portion of the labia majora which was separated by the root of the organ, as well as the lower portion of the mons veneris. I introduced a silver probe along the fissure before alluded to, to the distance of about an inch, where the fissure terminated by the apparent union of its lips, forming a cicatrix, which resembled somewhat the raphe of a scrotum. This raphe extended to what should have been the position of the posterior commissure of the vulva in the female. I found the orifice of the urethra near this place; and introduced a female catheter into the bladder, when there escaped through it about a teacupful of urine. Withdrawing the catheter and inserting it again, at a point a few lines below the orifice of the urethra, I gave it a direction downwards, instead of that of the urethral canal, and found no difficulty in inserting it its whole length into a cavity where its point could be freely moved in any direction. On taking it out, the lower portion was filled with a dark-coloured fluid resembling blood—the menstrual fluid which had there accumulated. The lower portion of the labia externa presented a rugose, flabby appearance, and with the raphe dividing them, resembled very much a scrotum deprived of testicles. This condition of the labia was doubtless produced by the collection behind them of the fluids escaping from the womb, causing them to act temporarily as the outer walls of a sac containing fluid, the pressure of which varied with the position of the body. I learned from the individual that the escape of fluid from the vagina was irregular, and depended upon the attitude of the body, the only outlet being the small orifice just beneath the urethral opening. There were, however, periodical returns of all those symptoms which accompany menstruation, and so marked as to have attracted the attention of the elder female servants. I also learned that the organ was subject to erections; and that she had desires for the female sex, but had been deterred from attempting connection by an apprehension that her deformity would be discovered.

Thus it appears that this "curious case of hermaphrodism" has been proved to be a case of occlusion of the vagina, accompanied with hypertrophy of the clitoris.

An operation was proposed; but when I stated that it would entirely change the assumed sex, she opposed it with so much earnestness that it was not insisted upon. [*The Stethoscope.*]

SURGERY.

PROFESSOR SYME'S OPERATION FOR TREATMENT OF STRICTURE OF THE URETHRA BY EXTERNAL OR PERINEAL INCISION.

The Treatment of Stricture of the Urethra, by external incision, as advocated by PROFESSOR SYME, of Edinburgh, in his pamphlet published in 1849, has called forth the controversial energies of zealous partizans and opponents. In the various communications on the subject, which have appeared in the medical journals, there is much that will repay perusal. The following are the articles most likely to prove interesting :—

SYME, Professor, *Lancet*, Feb. 17, 1849 ; April 20, 1850 ; May 18, 1850. (The latter article contains Mr. Syme's challenge to the London surgeons to send him a case of *impermeable* stricture.) Cases in *Lancet*, January 25 and Feb. 15, 1851. Mr. Syme's views were fully laid before the readers of the LONDON JOURNAL OF MEDICINE, p. 35, vol. for 1850.

FERGUSSON, Professor, Case with Lithotomy. *Lancet*, Feb. 16, 1850, and May 11, 1850.

SMITH, Mr. Henry. *Medical Times*, Sept. 15, 1849, May 4 and 25, and June 1, 1850.

PARTRIDGE, Professor. *Lancet*, April 13, 1850.

COCK, Mr. Edward. *Lancet*, June 29, 1850.

WADE, Mr. Robert. *Lancet*, January 26, 1850.

LIZARS, Mr. John. Cases Illustrating the Failure of the Operation for Perineal Section. *Medical Times*, October 26, 1850.

PROFESSOR MILLER has published in the *Lancet* for March 22, 1851, a paper lately read by him before the Medico-Chirurgical Society of Edinburgh. It is an excellent essay ; and contains a fair summary of the arguments for and against Mr. Syme's operation. As Professor Miller has disentangled the subject from many offensive personalities, with which others had overlaid it, we hope in future to see it properly discussed.

The author commences by referring to the fact, that perineal incision had long been practised and recommended by the late Sir Everard Home, by Sir B. Brodie, Dr. Jameson of Baltimore, the late Mr. Liston, and other eminent surgeons. He quotes passages from their writings to shew that this opera- "has not wanted the sanction of good surgeons. At the same time, it is worthy of note, that the operation is spoken of as sometimes difficult, by no means free of danger, and not warrantable unless the other and more ordinary means of cure have been tried, and found ineffectual." Mr. Miller has himself had occasion to resort to this procedure in two cases ; in one, the patient died, on the nineteenth day after the operation, of pyæmia, which was at the time prevalent in his wards ; in the other, the patient recovered.

He then proceeds to discuss the peculiarities in the modification of the operation lately proposed and practised by Mr. Syme. These are twofold :— 1. "An instrument is passed through the stricture, on the groove of which instrument, as a director, the stricture is divided. 2. The operation is *extended* to other cases than those which have actually proved intractable by other and gentler means ; rating the operation as one of *expediency*, in some measure, rather than of absolute *necessity*."

The first-mentioned peculiarity implies that *all strictures are permeable*, not only to urine outwards, but also to an instrument inwards. Mr. Miller observes, that most authorities agree that actually impermeable strictures are very few ; but that there is indisputable evidence of their occasional occurrence, as appears from the writings of Sir C. Bell, Mr. Liston, Baron Dupuytren, and Mr. Syme himself ; who, in the *Monthly Journal of Medical*

Science for 1844, published some cases of stricture, in one of which he mentioned, that "the smallest probe could not be passed". Having thus established the fact of the occasional occurrence of impermeable stricture, Mr. Miller makes the following judicious remarks :—

"The term 'impermeable stricture' seems to be an equivocal one. No stricture need be impermeable ; all may be forced, but with the risk of a false passage, and serious risks ensuing. A provincial surgeon, of great experience, used to boast that no strangulated hernia had ever resisted his hands ; with him the taxis never failed ; all cases were, to him, reducible. But such was dangerous practice ; and it seems to me that a similar risk must attach to the maxim, "all strictures are permeable". The student and young practitioner may be taught, that to fail with the instrument must always be a sign of deficient dexterity ; and, in consequence, they may be tempted to such a rashness of procedure as has been well deprecated by Sir Charles Bell. (*Surgical Observations*, p. 57.)[1] . . . Besides, a stricture which is at one time impermeable may, by spontaneous change, irrespective of all treatment, become permeable. An example of this is afforded by Mr. Syme, when he says that a case of stricture, which had been under the care of Mr. Liston, in the North London Hospital, and had obstinately refused to yield to that surgeon's efforts to pass an instrument, afterwards came under his own care in the same charity : and that he succeeded in passing an instrument into the bladder. Putting the manual dexterity, tact, experience, and general accomplishment of Mr. Liston and Mr. Syme on the same level,—an arrangement to which the latter gentleman will not object,—it follows that the stricture, at one time impermeable, at another time had ceased to be so, independently of curative treatment.

"On this part of the subject my belief is, that some few strictures there may and will be found, which are not, or ought not to be, permeable ; and that in these, rather than encounter risk by forcible propulsion of the instrument, it were better to perform the old operation."

With regard to Mr. Syme's extension of the operation of perineal section, Mr. Miller remarks that it is warrantable in such permeable examples only on two grounds ; first, that the cure will thus be rendered more rapid and certain than by other means ; secondly, that the plan of procedure is equally safe.

Mr. Syme's plan, the author thinks, is undoubtedly more rapid, but not more certain, in most cases of permeable stricture, than the rightly conducted treatment by instrumentation. Here he calls attention to two modes of using the catheter and bougie, well adapted to the final subjugation of cases even of great obstinacy ; viz. (*a*), the method of *tunneling*, as it may be called, by which the stricture is gradually penetrated by successive introductions of a No. 5, 6, or 7 bougie, made somewhat conical at the extremity, and allowed to remain for a longer or shorter time, according to the feelings of the patient ; and (*b*) tying in the catheter for forty-eight hours or thereabouts, a method well suited to gristly and resilient stricture : on withdrawing the catheter, a bougie of medium size may usually be introduced with comparative ease, and dilatation may be proceeded with. If it be objected that the tying in of the catheter is an irksome and formidable proceeding, the answer is obvious,—that no more is done, in this respect, than what is practised after perineal section ; and surely retention of the catheter for forty-eight hours is less formidable without than with a perineal wound.

In reply to the objection that "strictures so treated are prone to relapse", Professor Miller makes the following pertinent remarks. "In almost all cases, such relapse is not the fault either of the surgeon or of his system of

---

[1] "Of course I do not mean to infer that Mr. Syme practises the forcing of strictures, but only to express my fear that the unqualified enunciation of the maxim, 'all strictures are permeable', may lead the younger members of the profession to this procedure."

treatment, but of the patient himself. After having obtained half a cure, he grows irregular in his attendance, resumes careless living, perhaps lapses into dissipation, and does not return to regular treatment until recontraction of the urethra has warned him of his folly and risk. But let the dilatation be completed, till a full-sized instrument has on many occasions passed the whole canal unopposed; then let occasional introductions be maintained at gradually lengthening intervals, at the same time the general health, and especially the function of the kidneys, being carefully attended to;[1] and I believe that, under these circumstances, tendency to unusual resiliency and relapse will be sought for in vain. In other words, I believe that, in most cases of stricture, as perfect and permanent a cure may be obtained in this way as by any other means of treatment, however heroic that may appear."

As to the *safety* of the operation, Mr. Miller does not question that it has been safe in Mr. Syme's experience, but observes that "fatal results *have* occurred in other hands, both in London and Edinburgh. And it is not easy to see how a certain amount of risk can be avoided in such an operation. 1. By hæmorrhage. No doubt the safety here is to cut in the centre, and only in the condensed and solidified tissues which compose the stricture. 2. By urinary infiltration; and we know that very little of this may prove fatal, the urine acting as an intense poison on the system. 3. By abscess in or near the wound, leading perhaps to fistula, and irritative or hectic fever ensuing. 4. By intra-pelvic abscess. 5. By erysipelas. 6. By pyæmia."

The following are the general conclusions drawn by Professor Miller:—

"1. Most strictures are permeable; the great majority of these are curable by other and safer means than perineal section; and the metallic bougie and catheter, when rightly used, are neither so injurious nor so inefficient as Mr. Syme has represented them to be. 2. Permeable strictures, which refuse to yield to cautious and correct instrumentation, combined with suitable general treatment—strictures, also, which yield in part, but speedily and pertinaciously relapse—and strictures which are so impracticably irritable as absolutely to interdict the use of instruments, even with the aid of chloroform, opium, Indian hemp, nitrate of silver, etc.—such strictures may and ought to be treated by perineal incision, after the manner of Mr. Syme; *but such strictures are very few.* I may add, that strictures which, though bad, do not yet come altogether within the preceding category, may be subjected to perineal incision, when *time* happens to be an element of great importance; where the patient, for example, is a labouring man, and anxious to be as short a time as possible laid aside from the maintenance of his family. 3. Those strictures which are impermeable,

[1] "Mere handiwork will not succeed in stricture any better than in other complaints. There is no "*pure* surgery"; at least there ought not to be. The department of the surgeon is medico-chirurgical, not simply chirurgical; and every practitioner knows, that in no class of diseases is the aid of *medical* science more valuable, and indeed essential, than in those of the urinary organs. Many strictures may be prevented, and some may be cured, by medical treatment alone. And I have a dread of the terms "pure surgeon" and "pure surgery", as operating on the mind of the student; leading him, it may be, to neglect or despise that part of his professional accomplishment, without which he were but a fit representative of the barber-surgeon of a less enlightened day." [We are heartily glad to find so eminent a surgeon as Professor Miller thus strongly opposing the absurd idea, that there can be such a being as a "pure surgeon", or such a thing as "pure surgery". As the improvement of our profession advances, the day will probably arrive, when a "pure surgeon" will be thought of as an almost fabulous monster of antiquity; but, in the mean time, we must, with Mr. Miller, protest against the use of such terms, as they are liable to mislead the student, and cause him to neglect opportunities of acquiring indispensable knowledge, which can never be regained. EDITORS OF LOND. J. OF MED.]

or ought to be considered such—and they may be expected to prove still fewer—should be treated by perineal section after the old method."

As to Mr. Syme's monograph, Mr. Miller observes :—

"1. That, while he has overstated the risk attendant on the use of the metallic bougie and catheter in the treatment of stricture, he has underrated their efficiency. 2. That the operation proposed by him is admirably adapted for certain specified cases ; few in number. 3. That it is not applicable to all cases intractable by other means ; there being some strictures which are actually, or which should be considered to be, impermeable. 4. That the operation is not devoid of danger. 5. That progress towards cure thereby is not always smooth and uninterrupted. 6. That the operation will be found not always, and probably not often, sufficient of itself to cure. 7. That subsequently to the operation, instrumentation is required in the usual way ; the main use of the incision being, besides diminution of morbid irritability, to give the practitioner a good *start* in the use of the bougie, as after tying in a catheter. 8. When cure is completed, by instrumentation following on incision, dilatation may be expected to prove permanent ; inasmuch as such cure may not depend on mere expansion of the primal canal, but on something like reproduction of a portion of the urethra at the enlarged part..... The ordinary tissues at the part may be condensed, changed, and invested by a membranous lining, so as to cure the constriction by not merely dilating the old canal, but by *patching*, or *letting in* a new portion. Towards this end, however, it is very obvious that the use of the bougie, subsequently to the operation, is quite esssential.

"Or, further to condense, I believe :—1. That Mr. Syme's operation is a good operation, and an important addition to operative surgery, applicable to certain bad, very bad, strictures, which, however, are likely to prove, in the hand of a surgeon who practises all the departments of his art, and practises them all well, extremely few. 2. That those bad strictures, which are still worse, being impermeable, should be cut in the old way, and that such strictures are likely to prove still fewer. 3. That all other strictures—and these constitute a vast and overwhelming majority of all strictures—should be treated by instrumentation (catheter or bougie) variously employed, without incision."

MR. JOHN WALKER ON THE TREATMENT OF STRICTURES BY CAUSTIC POTASH.

The *Edinburgh Medical and Surgical Journal* for April 1851 contains a memoir, by Mr. W. Brown, of the late Mr. John Walker of Edinburgh ; from which we copy the following extract of a letter by Mr. Walker, relating to the use of Caustic Potash in Stricture. The date of the letter is 19th Feb. 1824.

".... The caustic used is potassa, which should be as perfect and uninjured as possible by the air's action. It must be reduced to fine powder in a small china mortar. To this add from a third to two-thirds of Spanish soap, also in powder. After incorporating them, a little soft water must be cautiously and gradually added, till it gets to the consistence of a paste or soft mass for pills ; it must then be put into a small wide-mouthed phial, firmly corked or stopped. I sometimes add a small quantity of very pure and finely-powdered opium, previously rubbing it with the soap ; but whether with any advantage, I cannot say. It will be well not to prepare much of the paste at once. I seldom prepare above a drachm or a drachm and a half at one time.

"In using it, take a small portion out with a silver knife or probe, and put it upon a bit of soft leather, which rub upon the holes of the instrument, till they are filled. Then wipe it clean with a soft rag, that the paste may be nowhere but in the holes. It must then be oiled, and introduced, with as much quickness as the feelings of the patient will permit, down to the

stricture, which you must now *enter;* and, after remaining a few seconds within it, move gently backwards and forwards three or four times, taking care not to go, if possible, beyond the limits of the stricture. After withdrawing it, I sometimes used to inject a syringe-full of warm oil, which soothes the parts; and generally give an opiate, which is preferable *per anum*, by means of a small one-ounce syringe, which will convey one ounce of mucilage, and 40 or 80 drops of laudanum, with great ease.

"Before introducing the caustic instrument, it will be proper to pass a full-sized common or silver bougie down to the stricture, but not to pass it. This widens the passages, removes spasm, and facilitates the introduction of the other.

"Should much pain, irritation, or suppression, take place from the use of the caustic, I need not say fomentations to the perinæum, and opiate clysters, will be required, with camphor mixture, three or four times a day.

"The slough produced by this caustic is quite different from that by the nitrate of silver. The latter is a tough tubular membrane; while by *this* it is gelatinous and bloody, as it acts at once, and dissolves the stricture, particularly if it is spongy and tender; of which we can readily judge by the feel in passing, by its bleeding readily, and by its being accompanied by a puriform discharge. When it is in this state, the potash acts powerfully, and brings away a great deal of gelatinous brownish slough.

"After the lapse of a few days, it may be well to examine the stricture by the bougie, so as to ascertain if you have gained ground, and determine both the propriety of another application, and the size of the instrument to be employed; because a single application may have been sufficient to put the stricture in a state to be afterwards managed by the bougie. At the same time, as this mode requires the instrument to be firmly grasped by the stricture, in order to its effectual action, we must enlarge the instrument as we gain upon the stricture; but we must also guard against undue irritation from the too frequent or too severe application of the caustic, and use as little of it as we can, till we know more of our patient, and what he can bear. Indeed, at all times, as a general maxim, I would say, never use the caustic when you can do your purpose by the bougie, though I know most strictures of long standing will not do without a few applications of the caustic; then the bougie acts with the utmost advantage, after the diseased surface is removed, which is the business of the caustic, not of the catheter.

"I have often been surprised at the effects of a single application of caustic, when I have not had an opportunity of examining the patient for two or three weeks after it has been used, and when, therefore, all irritation and swelling have left the parts. This should lead us not to be too hurried in renewing our applications; for, till the swelling subsides, we never can know what we have gained, and we had better act with caution. Though some recover much sooner than others, I should say a week is the usual time.

"I do not think the caustic acts so readily upon healthy parts as the nitrate of silver. If, after one or two applications, therefore, you find the instrument, when withdrawn, clean and without slough, I should be disposed to consider the parts much improved, and perhaps not requiring the use of more caustic.

"After withdrawing the instrument, it should be cleansed from slough, as well as caustic, by dipping it in hot water, and, with a bit of pointed wood, or tooth of a comb, cleaning the holes; and this will be completed by the aid of a brush, so as to remove all remains of caustic. The instruments are covered with leather slips, which I have used for many years. Too great attention cannot be given to preserve the polish of the instrument; the slightest touch is like a file to the delicate membrane."

[Mr. John Walker was a Fellow of the Royal College of Surgeons in Edinburgh, and was long a well-known practitioner in that city. He was

born in 1776, and was the son of Dr. John Walker, who was for several years Treasurer of the Royal College of Surgeons. After attending the lectures at the University of Edinburgh, and the practice of the Royal Infirmary and the Public Dispensary, he repaired to London in 1787. While there, he became a pupil of Cruickshanks, and subsequently of John Hunter. Of the latter he speaks, in his letters to his father, in terms of admiration; but with regard to the other lecturers, he appears to have been greatly disappointed, regarding the demonstrations of Mr. Cruickshanks as being "very confused, dry, and unmethodical, and far inferior to those of Monro". Mr. Walker was made a Fellow of the Royal College of Surgeons in Edinburgh, 15th September 1791. After practising in that city for many years, he died at Moffat in 1841, having for several years retired from the active duties of his profession.]

WILMOT ON STRUMOUS URETHRITIS.

In an instructive essay on some Affections of the Male Urethra, published in the *Dublin Quarterly Journal of Medical Science* for February 1851, Dr. S. G. Wilmot calls attention to a disease to which he gives the name of Strumous Urethritis. The symptoms are a constant discharge of watery matter, resembling whey, from the urethra, and a tickling or hot sensation in passing urine. These symptoms are heightened by drinking spirits, by sexual intercourse, or by exposure to wet, cold, and fatigue; and frequently an attack resembling acute gonorrhœa supervenes without any assignable cause. The lips of the urethra have a pouting appearance; they are not, however, circular as in gonorrhœa, but appear flattened laterally. The mucous membrane, as far as can be seen, resembles very closely the state of the palpebral conjunctiva in granular ophthalmia; and Dr. Wilmot believes that this condition extends as far as the bulb. On introducing a No. 8 bougie or catheter, pain is felt all along the passage, but especially at the bulb, where there is generally a soft spongy obstruction, capable of being surmounted by a little pressure on the instrument.

Dr. Wilmot looks on this affection as essentially strumous: and in a case which he recently had under his care, the patient had also strumous disease of both testicles. The disease, though independent of gonorrhœa as its cause, is very frequently preceded by that specific complaint, which glides gradually into it through the medium of gleet. A case of protracted gleet, in a person of well-marked strumous disposition, may therefore be expected to merge into the slow and obstinate disease just described.

When the disease is allowed to progress, the bladder very frequently becomes engaged; its irritability becomes increased, and there is a large deposit of pus in the urine. Dr. Wilmot has not had an opportunity of ascertaining whether the mucous membrane of the bladder presents the granular appearance; but he thinks it a rational conjecture that such is the case.

The urine is generally neutral; often slightly acid, and sometimes faintly alkaline: pus-globules are always detected by the microscope. It is often slightly albuminous; but it is difficult to determine whether this is from pus, or from the kidneys. Dr. Wilmot believes, that patients who have been long tormented with strumous urethritis ultimately die of renal disease.

In the treatment, Dr. Wilmot recommends the occasional introduction of a bougie, smeared, if there be not too much irritation, with some astringent ointment, especially the acetate of lead ointment. We may also employ injections of zinc, alum, or copper, or nitrate of silver; but Dr. Wilmot prefers the decoction of oak-bark, either plain, or with two grains of alum to the ounce. A little opium may be added, if there be pain or much irritation.

For the constitutional treatment, it is well to administer at first Plummer's pill and the iodide of mercury in small doses: but should the patient exhibit very marked scrofulous features, iodide of iron should be at once given.

Either of these medicines should be combined with extract of hemlock. Two grains of iodide of iron, and the same quantity of extract of hemlock, given three times daily for some time, have proved very beneficial. Nitro-muriatic acid may afterwards be given in decoction of bark or sarsaparilla. Sea-bathing, if the patient's health admit of it, should be regularly observed, and a generous system of diet ordered: ardent spirits, sexual connexion, over-exercise, and any other thing which increases the irritation, should be sedulously avoided. Where balsams and turpentine are persevered in, with the vain belief that the case is one of common gleet, the symptoms never fail to be aggravated.

NOCTURNAL ENURESIS TREATED BY APPLICATION OF NITRATE OF SILVER TO THE NECK OF THE BLADDER.

Dr. Demeaux has related, in the *Gazette des Hôpitaux*, some cases of nocturnal incontinence of urine occurring in adults, which he has successfully treated by one or more applications of nitrate of silver to the neck of the bladder. This remedy is probably very advantageous in incontinence of urine in puberty or adult age, for the affection is then of long standing and obstinate. But it would be barbarous to have recourse to this treatment in children, for whom belladonna is generally sufficient.[1] If this fail, we can still cauterise the urinary meatus, before proceeding to the operation on the neck of the bladder, which is not unattended with pain. [*Journal des Connaissances Médico-Chirurg.*, 1st March 1851.]

OBSTETRICS.

PROFESSOR SIMPSON ON REFLEX SENSATIONS CONNECTED WITH UTERINE DISEASE.

We quote, with slight abridgement, the following very lucid and instructive explanation of the so-called Sympathetic Pains which attend Uterine Diseases, from a clinical lecture by Professor Simpson in the *Edinburgh Monthly Journal* for February 1851.

The various pelvic symptoms (pains, difficult defecation or micturition, etc.) are, in some instances, mechanical in their pathology; in other instances they are sympathetic results. They may be present, and strongly marked, when the uterus is not unnatural in size or in position. In these instances (perhaps the more numerous class) we speak of the resulting disturbances of function, and increased sensations, as sympathetic or reflex; that is, as originating in an irritation primarily seated in the uterus and uterine nerves, but terminating and felt, secondarily, in the sensitive nerves of those other neighbouring parts which are affected.

In diseases of the uterus and its appendages, the principal pains and sufferings are often not located in the uterus or pelvis, but in other parts of the body, forming an important series of dynamic symptoms.

Sympathetic Pains in Different and Distant Parts of the Body. These sympathetic pains, or neuralgiæ, are often so marked as to draw away the attention of the patient, and even of the practitioner, from the real nature and seat of the malady.

Reflex motions are excited by excitation upon distant mucous and cutaneous surfaces, the impressions being conveyed by a nervous arc (which always passes through the spinal cord) to those muscles which are ultimately set into contraction; and these muscles may be situated in remote parts of the body. Morbid sensations, Dr. Simpson believes, originate often in the

[1] See London Journal of Medicine, January 1849.

same way; and we can as truly speak of reflex sensations as of reflex motions. A severe pain in the knee-joint frequently accompanies the early stage of morbus coxarius; and this pain cannot be explained on any mechanical principle, or by reference to any swelling in or around the diseased joint, compressing the nerves which supply the knee. The sympathetic or reflex pain occurs most generally in the commencement of the disease, when the lining membrane merely of the hip-joint is as yet affected, and when there is little or no swelling or effusion. An impression or excitation is conveyed from this affected membrane by the nerves which are distributed to it, and this impression is probably conveyed by them upwards as high as the spinal cord; and then another impression would seem to be reflected or conveyed downwards from the cord along another set of nerves,—viz., along the branches of those which are ultimately distributed to the knee-joint, the immediate seat of the so-called sympathetic pain. Or we may state the matter more correctly, by saying that the trunk of the nerve, going to the knee, has a morbid sensitive impression made on it somewhere during its course, as it passes through one of its higher plexuses, or at its origin in the cord itself, producing a change in it as if its own branches in the knee were painfully affected. Irritation of the mucous membrane of the bladder often gives rise to sympathetic or reflex pains in the orifice of the urethra, and along the course of the lower extremities. The small, red, granular, and very painful sensitive tumour, which sometimes grows at the orifice of the female urethra, is occasionally accompanied with distressing pain in the heel and sole of the foot. When the uterus is distended and irritated in pregnancy, the patient often complains of reflex or sympathetic pains in the lumbar region, in the mammæ, in the nerves of the teeth, etc. When the uterus is the seat of actual disease, such reflex pains are often very marked, and, at the same time, they are apt to deceive and mask the original and primary disease. The dependence of the reflex or sympathetic pains in uterine diseases upon the uterine irritation itself, as their primary source, is best seen in cases of displacement. By restoring a displaced uterus to its natural position, even though only temporarily, the attendant sympathetic effects are generally moderated or entirely removed. We cannot have the same precise proof in other uterine diseases, as ulcer, cancer, etc., because we cannot at once remove the primary irritation.

The following are the principal sympathetic pains under which patients, suffering from uterine disease, are liable to complain. They are enumerated, as far as possible, in the order of their frequency.

Pain in one or both Mammæ is very common in many forms of uterine irritation. It is often accompanied by some degree of swelling or tension in the gland; and occasionally the areola becomes somewhat darker and changed, as in pregnancy. These symptoms are particularly liable to be increased at the period of menstruation. If a patient complain of pain in the mamma, without evident local affection, the inquiry should always be directed to ascertain whether some diseased action is not going on in the uterus.

Pain under the Left Mamma, and upon the edges of the ribs of that side, is also very frequent, perhaps even more so than pain in the mamma itself. Dr. Simpson is inclined to believe it more common in uterine or ovarian disease in the unmarried, than in the married. It is probably as frequent in cases of uterine affections, as pain in the shoulder is in cases of hepatic affections. This pain under the left mamma is sometimes diffused along the side, but more usually it is limited, and the patient will say that she thinks she could cover the whole of the pained spot with a crown-piece. When not severe, it is not affected by respiration; but in more severe cases, it is increased by deep inspiration; and many a patient has been bled and leeched, etc., over and over again, under the idea that the pain was an indication of pleuritic inflammation, when, in fact, it had nothing to do with pleurisy, or any disease of the chest.

Pains in the Right Side, or right hypochondriac region, are much more rare, but are still sometimes to be met with.

Pain in some of the Vertebræ, imitating spinal irritation, is often also an accompaniment of uterine inflammation, and is not unfrequently combined with the pain under the left mamma. The patient principally complains of it when the part is pressed. Many suffering from these sympathetic vertebral pains, in consequence of uterine derangement or disease, have been laid up and counter-irritated with the moxa, cautery, etc., under the idea that there was actual spinal disease present.

Pain in the Lumbar Region, or in the Lumbar and Sacral Regions combined, is especially common as a sympathetic morbid sensation in uterine diseases, but particularly in those which consist of any displacement or enlargement of the organ. The great sacro-lumbar pain, which the woman in labour suffers in the same part, is itself entirely a reflex or sympathetic pain of the same character.

Pains in the Abdominal Parietes occasionally occur. Sometimes they are limited to one side, occupying the site of the ascending or of the descending colon. Occasionally they are confined to a limited spot. But, in other instances, the whole surface of the abdominal walls is tender and neuralgic. When this is the case, there is often also a greater or less degree of tympanitis, so as to suggest the presence of acute peritonitis, or of serious enlargement and organic disease of some abdominal organ. In some cases, the apparent tenderness is so great that the patient timidly shrinks under the least touch, and is even terrified at the approach and pressure of the hand of the practitioner.

Pains in the Extremities and Joints are sometimes secondary morbid results when the primary irritation or disease is seated in the uterus. Pain, stretching from the loins or pelvis downwards, along one or both of the lower extremities, is a very common symptom in uterine disease. In ovarian enlargement there is sometimes (particularly in the earlier stages of the disease) a morbid sensation of numbness and pricking in the corresponding limb; but this effect is probably mechanical, the consequence of pressure upon the nerves of the limb. Under the name of hysterical knee-joint, surgical authors describe a painful affection of that part, occasionally accompanied by swelling and apparent effusion, and which has often been mistaken for the common white-swelling. The pain, and other symptoms, are so chronic and so marked, as sometimes to have led the surgeon to amputate the limb for supposed incurable disease of the joint. Dr. Simpson is well assured, that in these cases the pain in the knee is almost always a secondary or reflex pain; and that the primary source of irritation will be found in some distant organ—very often, indeed, in the uterus or ovary. Similar pains in the other joints of the extremities are rarer, but are not altogether unknown. Dr. Simpson has had a patient suffering under chronic inflammatory ulceration of the cervix uteri, with profuse purulent discharge, and much pain and tenderness in the vaginal canal. But there was still more severe pain and tenderness of the skin and tissues over the head of the right radius. It sometimes deprived the patient of rest; and she maintained that it decreased and increased in correspondence with the changing state of the uterine irritation and discharge.

Pains in the face and head may also occur. Toothache, as a sympathetic pain, occasionally occurs during pregnancy; but Dr. Simpson has not had occasion to trace its connexion with uterine disease. Local and limited pains, as over one or the other eyebrow, in the forehead, in the occiput, in the temple (*clavus hystericus*), etc., sometimes appear to be the secondary consequences of uterine irritation. The headaches, however, under which uterine patients often suffer, are more frequently results of anæmia or functional derangement than of reflex or sympathetic sensation.

[The doctrine of *reflex sensations*, (so clearly expressed and illustrated in

the above,) is thus enunciated by Dr. C. J. B. Williams, in his *Principles of Medicine*, 2nd edition, p. 98, London: 1848:—

"Clinical observation teaches us that not merely motory impressions, but also those which cause sensations, may be reflected, so that when the impression is made on one part, the sensation is experienced in another. I do not allude to the fact that a stroke on the nervous trunk produces feelings referred to its branches, but I advert to impressions on the ultimate distribution of one nerve producing sensations in parts supplied by another nerve, or by another branch of the same nerve. . . The sensations cannot be referred to direct nervous communication, but to an influence reflected, probably from the spinal centre only."]

PLACENTA ADHERENT TO THE SCALP OF A MALFORMED FŒTUS.

Dr. Fletcher described this case, and exhibited the fœtus to the Birmingham Pathological Society. It is detailed in their *Ninth Report*, p. 33. The placenta adhered to the scalp, by a large portion of its membranous surface. The frontal and parietal bones were absent; the brain and membranes were healthy, and not unnaturally connected with the scalp. The nasal bones were absent; the alæ nasi separated for half an inch; the left nostril was open to the head. The left eye was small; the palpebral opening only three-eighths of an inch long; the right eye so small as to be hardly felt; the palpebral opening was obliterated. The upper lip was cleft. The left toes and fingers were defective. The age of the fœtus was eight months.

PLACENTA ATROPHIED AND CONTAINING CLOTS, IN A CASE OF ABORTION.

A healthy young woman, the mother of five children, who had never before aborted, aborted at the seventh month, six weeks after receiving a slight injury in the abdomen. Mr. Bindley exhibited the placenta to the Pathological Society of Birmingham; and in their *Ninth Report*, p. 36, it is thus described. "It was irregularly lobulated; one of the lobes contained a large coagulum; another portion was doughy and contained blood extravasated into its vascular network, which was degenerated into a pulpy mass. The whole organ was atrophied. The funis was thin; the vessels pervious."

MATERIA MEDICA AND PHARMACY.

TURPENTINE CONFECTION: COOKE'S FORMULA.

A Transatlantic cotemporary, the *Western Journal of Medicine and Surgery*, says that the following paste or confection, as prescribed by Professor F. E. Cooke, often succeeds as a diuretic when all others fail. "It is also very useful in diseases in which the mucous membrane is involved. There is a species of hoarseness which follows inflammatory affections, and which often approaches aphonia, in which this paste is a very valuable remedy." The following is the formula:—Castile soap, ʒiv; spermaceti, ʒviij; Venice turpentine, ʒvj; oil of aniseed, ʒiij; turmeric, ʒij; honey, q. s. Rub the soap and spermaceti well together, add the turmeric; after rubbing them well together, add the turpentine and oil of aniseed; and then sweeten with the honey. *Dose.* A piece the size of a nutmeg is given two or three times a day.

SEED OF THE WATER-MELON (CUCUMIS MELO).

Dr. Hook of St. Matthew's, South Carolina (U. S.), bears strong testimony to the value of the seed of the water-melon as a diuretic. He recommends that two ounces of the seed be bruised, and a pint of boiling water poured upon them. Three or four ounces prove diuretic and demulcent. (*Boston Med. and Surg. Journal*, from *Charleston Med. Journal.*)

THE HOSPITALS OF LONDON. No. V.

BY DR. CORMACK AND DR. SEMPLE, ASSISTED BY NUMEROUS REPORTERS.

LONDON HOSPITAL.

PHYSICIANS. Dr. F. Cobb, Dr. A. Frampton, Dr. W. J. Little.

ASSISTANT-PHYSICIANS. Dr. Jonathan Pereira, Dr. P. Fraser, Dr. Herbert Davies.

SURGEONS. James Luke, Esq.; John Adams, Esq.; T. B. Curling, Esq.

ASSISTANT-SURGEONS. G. Critchett, Esq.; N. Ward, Esq.; J. C. Wordsworth, Esq.

THE LONDON HOSPITAL, which now stands in the Whitechapel Road, was originally opened under the title of the "London Infirmary", in the City Road, on November 3, 1740; but was removed to Prescot Street, Goodman's Fields, in the following April. The sphere of its operations having rapidly increased, the name of the institution was changed seven years after to that of the "London Hospital"; and, in 1752, the foundation of the present building was laid by Admiral Sir Peter Warren, Bart. In the beginning of 1758, it was opened for the reception of patients; and on the 9th December in the same year, the governors received a charter of incorporation from his Majesty George the Second.

This Hospital is situated nearly in the centre of the Tower Hamlets, a borough containing a population of about 400,000, and is in the vicinity of the Docks and some of the most important and extensive manufactories of the metropolis. From this circumstance it arises, that a large proportion of the cases which come under treatment are *accidents;* the docks giving, on an average, one accident a day. The London Hospital may therefore be considered as the great *surgical* hospital of the metropolis. It contains four hundred beds, which are thus classified, viz.:—

Male Accidents	130
Do. Surgical cases, not being accidents	40
Do. Medical cases	63
Female Accidents	35
Do. Surgical cases, not being accidents	33
Do. Medical cases	44
Hebrew Wards (Male)	11
Do. Do. (Female)	10
Children under seven years	20
Attics—for cases of Fever or Delirium tremens	6
Operation Wards (Male)	4
Do. Do. (Female)	2
Extra Do. for Male or Female as required	2
	400

Owing to the large proportion of accident cases received, the number of patients under treatment in the house at one time varies very considerably, it having ranged in one year from 253 to 396. During the year 1850, the average number of patients in the house was 320.

The following is a table of the number of accidents admitted during the years 1842—50, both inclusive.

Years.	Fractures.	Wounds.	Contusions.	Sprains.	Dislocations	Concussions.	Burns and Scalds.	Hernia.	Bites of Dogs.	Suicidal attempts and Poisoning.	Various.	Totals.
1842	840	1042	2141	567	97	52	265	75	58	38	328	5503

Of the 114 deaths, 13 occurred on the first day of admission, viz. :—

Fractures	4
Wounds	1
Contusions	2
Concussions	3
Burns	3
Total deaths 1st day	13
„ 2nd „	18
„ 3rd „	17
„ 4th „	8
„ 5th „	7
„ 6th „	2
„ 7th „	4
Total deaths in 1st week	69

Of the 9199 cases of accidents admitted during 1850, 2222 were in-patients, and 6977 out-patients. Of the in-patients, 1936 were discharged cured ; 114 died—13 upon the first day, and 69 within the first week ; and 172 remained in the hospital at the end of the year.

The relative mortality in the London Hospital is low ; and this is probably in a great measure due to the open situation in which it stands. We copy a return of the number of patients admitted each year into the wards, from 1835 to 1850, both inclusive, and also the number of deaths in each year.

Date.	No. of Patients.	Deaths.	Per cent.	Date.	No. of Patients.	Deaths.	Per cent.
1835	2735	277	10	1843	3530	244	7
1836	2815	309	10·5	1844	3691	224	6
1837	2961	418	14	1845	3625	228	6·25
1838	2987	371	12·5	1846	4092	280	7
1839	3247	305	9·5[1]	1847	4159	276	6·6
1840	3339	296	9[2]	1848	4185	263	6·25
1841	3308	331	10	1849	4090	298	7·25[4]
1842	3300	260	8[3]	1850	3894	277	7

The mortality for 1850 may be thus apportioned :—

Physician's cases	127 deaths.	11·66 per cent.
Surgeon's ditto (accidents)	114 „	5 „
„ „ other cases	36 „	6 „

It hence appears, that the relative mortality among the medical cases is much greater than among the surgical cases or accidents.

The wards of the Hospital are ventilated by simple round ventilators in the ceilings, communicating with air-bricks in the walls. The windows are opened slightly at the top when necessary. There is no hot air in use ; the wards are all heated by open fire-places. Water is supplied from the East London Waterworks, by high pressure, to cisterns on the roof. Hot water is laid on throughout the house, from cisterns on roof, heated by steam from boilers in basement. There is a bath-room, with all apparatus complete, to each of the eight divisions into which the wards are classed. There are also bath-rooms for out-patients ; and a medicated bath is prepared for in or out-patients, as required.

[1] This year new sewers were completed (about August).
[2] This year the hot air was discontinued in the wards (at Christmas).
[3] This year the new wing was opened.
[4] This year the cholera prevailed.

The expenditure of the hospital is, on an average, £15,000 a-year; and, to meet this, the total fixed income is only £10,000, leaving £5,000 per annum to be made up by private subscriptions, donations, etc. In 1850, the expenditure amounted to £14,472 : 12 : 11, and the receipts to £13,522 : 6 : 5, leaving the expenditure in an excess of 950 : 6 : 6 over the income. The cost for each out-patient is about 1 : 8¾; *i. e.*, about 7½ for surgery, and 1 : 1½ for Dispensary, including brandy, wine, etc. The cost incurred for the in-patients (including the amount expended in repairs, extensions, and improvements, which, for some years past, have been necessarily very heavy), was £12,754 : 9 : 5, or £3 : 5 : 6 per head.

The pecuniary resources of the London Hospital have fluctuated greatly at different periods, and its utility has thereby been much limited. In 1807, the available income having been reduced to £2,840, and the patients to 130, an appeal was successfully made to the benevolence of the public. In 1814, a second appeal enabled the governors to complete the west wing, and receive an additional number of patients. The centenary festival, in 1840, presented an appropriate occasion for another appeal, which was very successful. The extension of the east wing was completed in 1842; but even now the income is insufficient to enable the committee to extend the benefits of the building. During 1850, 196 applicants, certified as proper cases for admission, were rejected from this reason.

Besides special arrangements for Jewish patients,—a large number of the subscribers belonging to the Hebrew persuasion,—there are, in connexion with the Hospital, a Samaritan Society and a Medical School.

The Samaritan Society was established in 1791, at the suggestion of the late Sir William Blizard. The objects of this benevolent institution are well expressed in a document appended to the last report of the hospital, the substance of which we now give.

Domestic servants, mechanics, and labourers, are often obliged to quit their places to go into the Hospital; and, when discharged convalescent, are often without a friend or home. For the relief of these—and especially of young females—this Society affords its aid. Many, who have expended all their money, or even pawned their clothes, previous to admission, in order to support themselves and obtain medical assistance, are, under such circumstances, aided by the Samaritan Society; relief is also occasionally afforded to the families of patients living at a distance. For those patients from a distance who, on their recovery, have not the means of returning home, applications are made to societies instituted for the express purpose, or places are taken, and the fares paid, by such conveyances, as are most suitable to their different stations in life. Beds are regularly engaged at the Margate Sea-Bathing Infirmary, for such as require the benefits of that institution; and, where necessary, mechanical apparatus are afforded to those who have undergone operations, or have been the subjects of partial loss of sight, or of rupture from sudden causes. Patients who are destitute of sufficient clothing are relieved. For servants whose conduct has been good while in the hospital, exertions are made to procure situations; and a great number of sailors and labourers have employment procured them, by letters addressed to captains of ships, dock-masters, and others, who have work at their disposal. Extra-diet and other comforts, such as no medical institution can with propriety or convenience afford, are occasionally administered. Many also of the out-patients, as well as the families of those within, are visited and relieved.

In 1822, a library for the use of the in-patients was commenced, at the Society's expense, by the purchase of between 300 and 400 volumes; and has since been increased to nearly 600 volumes, consisting of works of piety and religious instruction, biography, natural and general history, and select works of useful and interesting information.

The Samaritan Society possesses about £15,000 funded property. The following is a general account of the relief afforded by it from 1st March 1850, to 28th February 1851.

442 Patients relieved with money, or by having various necessary expenses paid	£363 : 10 : 0½
Clothing supplied	4 : 0 : 9
Mechanical aids	42 : 16 : 5
	£410 : 7 : 2½

Medical Instruction. The lecture building is situated at the east end of the hospital, and consists of a theatre, an anatomical and pathological museum, chemical lecture room, and dissecting room. There are teachers of all the ordinary branches of medical science. The anatomical museum is open to the students daily from 11 A.M. to 2 P.M.

Clinical instruction is given by the physicians and surgeons, and consists chiefly of short observations on the cases at the bedside, and occasional lectures on cases of interest and importance.

ROYAL LONDON OPHTHALMIC HOSPITAL, MOORFIELDS.

Purulent Ophthalmia of Newborn Children. (Reported by James Cummin Toshach, Esq., M.R.C.S.)

No one can witness the practice of this great Ophthalmic Hospital, without being painfully struck with the lamentably frequent loss of sight from purulent ophthalmia in newborn children,—a disease entirely within the control of very simple remedies, if early applied. It may be useful to call attention to this disease, and its appropriate treatment, because instances are frequent, in which medical men overlook its early stages, or fail to employ the suitable measures of relief. The patients are peculiarly attractive of pity, from their tender age, their utter helplessness and unconsciousness, and the terrible consequences to which ignorance or neglect exposes them. Were the community, and the members of our profession, aware how large a proportion of blind persons owe their calamity to this very tractable inflammation, greater efforts, we imagine, would be made to inform and tutor the parish midwives, or other attendants on the very poor, to be on the watch for its first approach, in the children of women suffering from vaginal discharges, and to adopt without delay the requisite precautions to cut it short or subdue it.

Commencing usually on the third day after birth, and attaining its height at periods varying from the seventh or eighth day to three weeks, it affords ample time to interpose the necessary relief. But this precious interval is too often allowed to elapse without anything being done, beyond the most imperfect cleansing, the application of warm water, or that popular remedy—the mother's milk—while enormous quantities of creamy pus are accumulating behind the lids, which are spasmodically closed upon the eye, and keep it bathed and pressed upon by the morbid secretion. No doubt, the original intensity of the disease varies much, either from differences in the constitutional strength of the infant, or more probably and more often from difference in the strength of the virus, to which, we believe in common with most writers, this inflammation may be traced. But in numerous cases, the delay of which we speak is more than sufficient to establish beyond recall those destructive changes in the texture of the cornea, and possibly of deeper parts, which entail certain and irreparable blindness. And how truly painful is the task then imposed upon the surgeon, to announce to the nurse, or perhaps the mother of the little sufferer, that already the time has passed when the eye might have been saved; that they have sought relief too late, and that the child is consigned to a life of darkness.

To show that we are not exaggerating the importance of this subject to the community, we shall here subjoin a table, shewing at a glance the chief particulars of some cases of purulent ophthalmia that presented themselves in the practice of Mr. Bowman in the course of one year. These cases are selected in consequence of their shewing the results of neglect or bad treatment; many others applying early, and treated in the way presently to be mentioned, escaped with perfect sight. The number of cases of purulent ophthalmia of children treated annually at this Hospital is over 200.

Duration of Disease.	Treatment previously pursued.	Condition of Eye when brought.	Result.
A. 11 days.	Nothing done.	Right cornea sloughing.	Partial leucoma, anterior synechia, strabismus commencing.
B. 3 mths.	Warm water and mother's milk.	Both leucomatous, with tendency to staphyloma.	Staphyloma of whole of right, universal leucoma of left, not bulging.
C. 3 weeks.	Warm water, astringent dps.	Right cornea clear; left given way from a slough	Staphyloma of left followed, but subsided without operation. Leucoma is now flat, and globe half shrunk.
D. 10 days.	Warm water. Lard at night.	Right cornea sloughed; left clear.	Right eye lost, left cornea clear.
E. 1 mth.	Milk and water. Poultice.	Both corneæ sloughing; both upper lids everted	Left cornea leucomatous, right nebulous, lids righted.
F. 1 year.	Solid arg. nit. several times applied for first week.	Staphyloma of both, especially of left.	
G. 3 weeks.	Warm water.	Both corneæ partially sloughed; left worst.	Synechia anterior with leucoma in both; in right are three minute opaque white dots on the anterior surface of the lens, one of which is central. The left pupil is small, much of pupillary border being adherent to the leucoma.
H. 1 year.	Nothing done for a fortnight.	Staphyloma of right; left cornea destroyed; and front of globe flat.	
K. 5 weeks.	No treatment.	A puny child; difficult to ascertain the state of the cornea.	Died in convulsions.
L. 6 weeks.	Drops from a druggist.	Right cornea nebulous.	
M. 7 weeks.	Born in workhouse. Drops used twice a day.	Central leucoma of the right cornea.	

The treatment which is pursued at the Royal London Ophthalmic Hospital, in these cases, is simple and effectual. It consists, in general, of nothing more than the frequent injection over the front of the eyes, between the lids, of a solution of alum (alum gr. iv, water ℥i), and then anointing the lids with lard, to prevent adhesion. If the inflammation is very severe and recent, the first syringing is with a solution of nitrate of silver (gr. iv to ℥i, never stronger), and afterwards with the alum; the latter being thrown over the conjunctiva so as thoroughly to cleanse it, every half hour, every hour, or every two hours, according to the intensity of the inflammation, and the rapidity with which the purulent secretion is renewed. After

each syringing, the lard is applied, so that the lids may not agglutinate in sleep. No leeches, blisters, or other auxiliary means are used; nor is the solid nitrate of silver, or strong ointments of it, ever employed. Leeches, though sanctioned by even so judicious an authority as Dr. Mackenzie, are deemed unnecessary; and they are certainly hazardous at this tender age, and in this situation, especially among the poor, treated as out-patients. And the astringent solution, of moderate strength, is considered at least equally efficacious with the solid caustic, while it gains more uniform access to all parts of the inflamed membrane, and it is a safer and less painful remedy.

The effect of this treatment is soon apparent, in a decided diminution of the discharge, and its more gleety nature, in lessened vascularity and intolerance and spasm, as well as in the altered temper of the infant. A few days are generally sufficient to produce these results, and the subsequent progress is steadily onwards to recovery. And the advantage of it is, that it is equally applicable in all periods of the inflammation characterised by purulent discharge. If used early, it saves the eye; if delayed till the cornea has suppurated or ulcerated, or the iris or lens protruded, it has the salutary effect of arresting the disorder, and preventing further destruction. And a very great advantage indeed is this—one perhaps hardly predicable of any other remedy in any other disease—at least to the same extent. The simplicity of the treatment, and its general appropriateness to all forms and stages of the disease, should serve to give it currency among those little conversant with eye diseases; and may even sanction its use by the parish midwives as a nurse's remedy; of course only where the aid of a regularly educated medical man cannot well be had.

It may not be out of place to indicate the best means of performing this little operation of syringing within the lids—an operation easily performed badly; and, if badly, as well not done at all. The infant is laid on its back, the head on one side, the cap off, the clothes thrown off the neck, so as to escape being drenched. The head being held between the knees, the lids are gently opened by separating the finger and thumb placed on each, and resting on the margin of the orbit, so as not to compress the globe; and the fluid is then thrown in different directions between them, so as to wash the whole inner surfaces, and clear out the pus. It is well to use a four ounce syringe, which can be worked with one hand. The nozzle should be rounded, and its bore very fine. A single charge of the instrument is then sufficient for the entire operation, and the whole is performed with celerity, effect, and safety.

It must not be inferred, because no mention is made of them, that medicines are not administered internally. Particular attention is always given to the state of the bowels, to the constitution and habit of body; and such remedies as seem to be appropriate are prescribed.

GUY'S HOSPITAL.

[COMMUNICATED BY DR. GROWSE, M.B.LOND.]

The OBSTETRIC DEPARTMENT of Guy's Hospital, under the immediate superintendance of Drs. Lever and Oldham, comprises two distinct portions:—1st. That which provides for the efficient attendance of Lying-in Women; and 2ndly. That which relates to the Treatment of Diseases of the Womb and its Appendages.

The Lying-in Charity, established in the year 1833 by Mr. Harrison, the late Treasurer of the Hospital, has since that time undergone many and highly important alterations in its organisation, and has lately been brought to such a condition, that, while it provides the most efficient attendance upon those women who choose to avail themselves of its services, it, at the same time, affords to the student the largest opportunities of acquiring a thorough

knowledge of the art and science of obstetrics. He is endowed with just so much responsibility, as may enable him to feel that amount of interest which is essential to the competent fulfilment of his duties.

Such persons as live within a convenient distance from the hospital, and who are, from their position in life, entitled to the benefits of the charity, are provided with attendance and medicines, at their own houses, during the puerperal state; and a limited number, upon the recommendation of the attendant, are allowed such necessaries of diet as may be considered requisite to further their convalescence. Moreover, as the poverty of some disables them from procuring that amount of linen, which is essential to cleanliness and comfort, the charity affords them the loan of a sufficient quantity, upon the recommendation of any respectable householder.

All persons are requested to make their applications for attendance, at the office of the charity, between the hours of 10 A.M and 12 A.M., on any day, with the exception of Sunday, Tuesday, and Saturday. Their names are then entered in books provided for that purpose, and a registry is at the same time made, of the place of residence of each, her present age, and that at which she married; the number of children she has had, their respective sexes, and whether born dead or otherwise; the number of miscarriages, or abortions to which she has been subject; her country, complexion, and the character of her previous labours. A card is then given her, containing her name and address, which she is desired to send to the charity upon the supervention of labour, when she will be provided with immediate attendance.

The scholastic staff of the charity, under the surveillance of the Obstetric Physicians, consists of three resident obstetric clerks, who are appointed by the Treasurer, upon the recommendation of the Physicians, and a further corps of gentlemen anxious to attend upon cases. The former are provided with rooms and commons, and are chosen from those students who have, during their pupilage, evinced the greatest regularity in their attendance upon lectures, who have devoted themselves with the greatest diligence to the opportunities afforded them of acquiring a practical knowledge of this branch of their profession, and who have attained the largest amount of general proficiency.

The Senior Clerk holds office for the space of one month. He must be a member of the College of Surgeons, or a licentiate of the Apothecaries' Company, and must have filled the office of Second Clerk. It is his duty to provide a competent assistant staff, and to see that every person, who demands the services of the charity, has efficient and speedy attendance. He is, moreover, expected to hold himself ever in readiness to attend any call for assistance, real or imaginary, which may be made upon him; and with the sanction, or in the presence of the Obstetric Physician, he is permitted to use such means, instrumental or otherwise, as may be deemed necessary for the furtherance or completion of labour. In addition, he is responsible for the due entry of all cards and certificates in their proper books; and, at the expiration of his month of office, is expected to render to the Treasurer and Physicians an account of the proceedings of the charity during that period.

The Second Clerk holds office also for one month. He must be a member of the College of Surgeons, or a licentiate of the Apothecaries' Company, and must have filled the office of Junior Clerk, or be especially recommended. It is his province to render his assistance, upon application, in all cases, real or otherwise, of disease, or tardy convalescence supervening upon delivery; to see that all proper cases are reported, and to enter the certificates of attendance, with any remarks upon the nature or complications of the labour, which may be made by the attendant. Should the Senior Clerk be pre-engaged, he is expected to discharge his duties; and at the expiration of his month of office, is established by the Treasurer, upon the recommendation of the Physicians, as Senior Clerk.

The Junior Clerk is in residence for a fortnight. It is his duty to attend all cases that occur during the night; and, during the absence or pressing engagement of any gentleman on duty during the day, to undertake the management of those cases which would otherwise have fallen to his share.

The Assistant-Staff consists of a corps of students, eight in number, each of whom undertakes to attend all cases which may occur in any stated two hours between 6 A.M. and 10 P.M.; in addition, there are several gentlemen who enter their names at the office, for the purpose of undertaking the management of casual cases occurring during the night or day in the absence of the junior clerk or gentleman on duty.

Since the formation of the charity, the number of women who have been attended by the students attached to the hospital has continued steadily and progressively to increase. Thus, during the first seven years after its establishment, 4666 were attended; during the second seven years, 6008; and from Oct. 1847 to Oct. 1850, no less than 4055 poor women availed themselves of the benefits of this institution; and, inasmuch as in almost every month more women enter their names than are attended during the same period, there is a certainty of much further enlargement.

For the treatment of such diseases as are peculiarly incidental to women, two wards are set apart, each containing ten beds. Into these, patients may be admitted, when a vacancy occurs, every Wednesday, at 10 o'clock A.M., on their making application at the Hospital; such cases having the preference as shall be found upon examination to be the most severe, and at the same time amenable to treatment.

Each obstetric physician has his separate ward, and is assisted in his duties by a clerk, who is chosen from such of the students as shall appear to the physician to be the most deserving, and whose character will bear the strictest investigation. It is his province to accompany the physician when he visits the ward, and assist him in his examinations, whether manual or otherwise, either of the in or out-patients; and in his absence, to prescribe such remedies as may be necessary for the amelioration of urgent symptoms. He is, moreover, required to see that any application which may be thought requisite is delicately and properly made, and to keep a correct report of all cases which are admitted during his month of office.

Drs. Lever and Oldham attend every Saturday morning at the hospital, for the purpose of seeing and prescribing for out-patients. The latter begins his duties at 10 A.M., and the former two hours later. A limited number of letters (twenty) are allowed to each physician, and these are distributed to those patients whose cases appear the most to require treatment. Every letter is presentable four times, unless the patient shall have failed twice in her attendance, when the letter will be taken from her, and she will be considered as a defaulter, and have to run the same risk with others in procuring a fresh one. Upon each of the letters, the name of the physician under whose care the patient may be, is printed, and a registry is kept upon it of the date of attendance, with the name, age, residence, and occupation of the woman or her husband; a card is at the same time given her, bearing the number she holds among the out-patients, and this she is required to present at each separate attendance.

Amongst the cases which present themselves, the diseases, and the modes of treatment of each class under its peculiar conditions, are too various, and would take up too much space to be included in this short report.

REPORTS OF SOCIETIES.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Tuesday, February 25, 1851.

Dr. Addison, President, in the Chair.

Case of Small-pox occurring a Third Time after Vaccination, and proving Fatal. By John Webster, M.D., F.R.S. Three well-marked examples of the recurrence of small-pox, met with in the same family, were related, one of which terminated fatally. The case especially referred to by Dr. Webster was that of H. N. N., who had been vaccinated satisfactorily in 1827, when three months old. Notwithstanding this circumstance, he was attacked by small-pox in 1833, along with an elder brother, who had been likewise vaccinated. Both patients recovered. In 1838 the two lads were again attacked by variola, along with a third brother, likewise regularly vaccinated. All three got quite well in due time. Subsequently, Mr. H. N. N. went to India in the Company's service, where he was seized, in April 1850, with the usual and well-marked symptoms of small-pox, which soon became confluent, and proved fatal at Dharwarinth, on the 13th of that month; this making the third time this gentleman had been attacked by variola, although previously vaccinated.

Case of Confluent Small-pox after a Third Vaccination. By Dr. A. P. Stewart. Case. A gentleman, 25 years of age, who had been five years apprenticed to a gentleman in extensive general practice in Devonshire, had been most successfully vaccinated when six months old. Requiring to attend variolous cases, he had the operation repeated in July 1849, without effect, and again in May 1850, with much irritation, inflammation, and swelling of the arm, the lymph from the vesicle not communicating the disease. He came to London to begin his medical studies on the 13th of October last, having been exposed to infection the same morning. The train of premonitory symptoms set in on the 15th, and was followed (on the 17th) by the appearance of a closely-packed eruption of papulæ all over the body. For four successive nights, mild delirium was present; but the sore-throat and conjunctivitis, occasioned by the presence of vesicles, were quickly relieved by the application of a solution of nitrate of silver; and the pulse, previously as high as 120, never rose above 100 after the seventh day. The vesicles, though very numerous on the hands and feet, caused little or no pain; on the eleventh day of disease, and the seventh of eruption, they were at their height; and, in the course of the next two days, had nearly all dried up and scaled off, with very trifling discharge. Convalescence went on rapidly.

Dr. Stewart referred to the prejudice which existed in many parts of England against vaccination, and the extent to which inoculation for small-pox, in spite of the law, prevailed. The conclusion drawn was, that vaccination offered more protection against secondary small-pox than did inoculation, for the mortality was much less in those persons who had been vaccinated than in those who had been inoculated.

Dr. Mayo spoke of an epidemic small-pox at Edinburgh some years since, in which the disease was confluent, and more fatal among the inoculated than among the vaccinated, the difference in favour of the latter being remarkable. Cases of small-pox after vaccination did not lessen the value of that operation. In three cases of supposed measles, at the Middlesex Hospital, the exanthem proved to be secondary small-pox; and he believed that many cases, reported to be second attacks of measles, were really not such.

Dr. Gregory observed, that in the first case, the fatal attack of small-pox occurred in India, where the intense heat rendered that disease especially dangerous. In Dr. Stewart's case, revaccination had been tried, and had caused great inflammation; nevertheless, the patient was again attacked with small-pox, showing the little use there is in revaccination. He had long been of that opinion. Inoculation gives the disease, small-pox; and, although some may be attacked again, it is generally protective for life. Vaccination protects up to puberty; but after that a change takes place, and the individuals become liable to small-pox. In 1815, when those first vaccinated in infancy attained the period of puberty, modified small-pox was first heard of, and it has since continued to occur. Such cases are continually admitted into the Small-pox Hospital, and their mortality has been found to be five per cent. He did not consider the cicatrices a good test of perfect vaccination. When they were complete, they were satisfactory; but their imperfect condition would not imply equal imperfection in the operation, as that might be the result of subsequent local inflammation, the constitution being still protected. Vaccination, however, should not be discouraged, because it served to protect one-half the population, statistics showing that one-half of those born die before puberty.

Dr. Webster was of opinion, that in many cases where small-pox occurred after vaccination, that operation had been imperfectly practised. In his case, it was remarkable, that the second attack of the disease involved several members of the same family, but the sons only; the daughter escaped. It would seem as if certain families could not be protected; and a case mentioned by Dr. Macintyre would appear to confirm this opinion. Two young men, both vaccinated, went abroad. The one in India caught the disease, and died. The other, in South America, although he had been vaccinated and inoculated, hearing of his brother's death, was revaccinated; still he got small-pox, and nearly died.

Dr. Copland believed that vaccination was only a temporary protection, and that, as the person became older, its influence wore away.

Anniversary Meeting, March 1, 1851.

Dr. Addison, President, in the Chair.

It appeared from the Treasurer's report that the Society had exceeded its receipts during the past year by £308:7:10, the receipts being £1809:9:7, the expenditure £2117:17:5. After the special business of the day, the election of officers, etc., had been transacted, Dr. Addison delivered the Annual Address, in the course of which he feelingly alluded to those members who were lost to the Society by death during the preceding twelvemonth,—Dr. Prout, Dr. Haviland, Mr. Crosse, Mr. Malyn, Mr. Safford Lee, and Mr. Joseph Freeman. He read also a brief sketch of each of these gentlemen; that of Dr. Prout having been written by Dr. Golding Bird; of Dr. Haviland by Dr. Paris; of Mr. Safford Lee by Mr. Quain; and of Mr. Joseph Freeman by Mr. Green.

The following gentlemen were elected Office-bearers for the ensuing year. President. Joseph Hodgson, Esq., F.R.S. Vice-Presidents. Thomas Mayo, M.D., F.R.S.; John Thomson, M.D.; William Coulson, Esq.; Alexander Shaw, Esq. Treasurers. Robert B. Todd, M.D., F.R.S.; Richard Quain, F.R.S. Secretaries. Seth Thompson, M.D.; Campbell De Morgan, Esq. Librarians. Henry Pitman, M.D.; James Dixon, Esq. Other Members of Council. George Cursham, M.D.; Sir James Eyre, M.D.; William Macintyre, M D.; William Merriman, M.D; Alexander Sutherland, M.D., F.R.S.; James Clayton, Esq.; Henry Charles Johnson, Esq.; Henry Hancock, Esq.; John Hilton, Esq., F.R.S.; Andrew M. M'Whinnie, Esq.

Tuesday, March 11, 1851.

Joseph Hodgson, Esq., F.R.S., President, in the Chair.

Compression of the Fœtal Head during Birth. By T. Ogier Ward, M.D. The following were the main propositions. 1. Under all circumstances, almost without exception, the head of the child undergoes a change of shape during birth, from which it recovers in the great majority of instances immediately, from the elasticity of the bones, or from the effects of the first cries in producing determination of blood to the head. 2. In some cases, the head retains its compressed shape for an indefinite period, during which the child is apt to suffer from attacks of flatulence, convulsions, paralysis, and other cerebral affections. 3. There is reason to believe that idiocy and insanity may also be produced by this deformity of the skull, and the consequent compression of the brain, when it is not removed during childhood. 4. The most efficacious means of relieving the brain from this pressure is to excite the cry of the child after birth, and thus, by causing distension of the cerebral vessels, to promote expansion of the cranial bones. Thirteen cases were adduced in support of these propositions, of which four were cases of convulsions, one of symptoms of insanity, one of paralysis, that ceased when the head regained its form—and all suffered more than usual from flatulence. In two of the four cases of convulsions, the fits came on several weeks after birth, and were immediately followed by the restoration of the head to its normal shape.

Case of Chylo-Serous Urine. By J. Pearce, M.D., H.E.I.C.S. With an Analysis of the Urine. By J. E. Mayer, Esq., Madras Medical Service. Case. A woman, born in India of English parents, twenty-two years of age, the mother of three healthy children, had been nursing the youngest for ten months, when first seen by the author in March 1850. For the last five months the urine had been pale and milky, sometimes forming a jelly on cooling: the quantity had been rather large. The same state had been observed after her other confinements, and had ceased after weaning. On this occasion, she was recommended to wean the child when she first applied for advice. She declined, however, and was put on a course of tonics, with a generous diet. This plan was continued for two months, having been interrupted for a few days by a feverish attack. At the end of this time, no improvement having taken place, the patient removed to Bangalore, and came under the observation of the author. The quantity of the urine was at this time moderate; it was milky, formed a jelly when cool, and coagulated on the addition of nitric acid. The child was now weaned, the tonic plan of treatment continued, and in about three months the patient returned to her family, considering herself well. The urine was less milky, and did not coagulate on the addition of nitric acid, but still formed a jelly on being allowed to stand for some time without being agitated. The analysis, by Mr. Mayer, shewed that no casein, pus, or phosphates, were present, but that it contained albumen and an excess of fat; from which he inferred, that it is "to the presence of animal fat and albumen", that the milky appearance of the urine is attributable.

Tuesday, March 25, 1851.

Joseph Hodgson, Esq., F.R.S., President, in the Chair.

Necrosis of Bones of Cranium: removal of Large Portions. By John Drummond, Esq. Case. In 1845, a seaman belonging to H.M.S. *Mutine*, fell down some stone steps at Sierra Leone, receiving a contused wound of the scalp, for which he was admitted into the Royal Naval Hospital at Plymouth, in October of the same year. The bone, which had not been supposed to be injured, was found denuded of its pericranium to some extent, on the left side of the occipital region. After an attack of erysi-

pelas, followed by numerous purulent deposits under the scalp, necrosis went on rapidly; there was oozing of pus from beneath the diseased bones, and gaping of the coronal and sagittal sutures, the brain pulsating very distinctly in the spaces. In July 1846, he was removed to the Melville Hospital at Chatham. During the six years he has been under observation, there have been repeated attacks of erysipelas, followed by profuse suppuration. Both tables of the skull have suffered in some places; in others only the external. About five square inches have been lost from the frontal and right parietal bones, and from the squamous portion of the right temporal. The whole of the occipital bone, to within an inch of the foramen magnum, is deficient, except about two inches in the centre, which are in process of separation. On the left side, there has been less destruction of the bones; but extensive caries is going on there, and fœtid pus is discharged from several openings. At no point does there appear to have been any tendency to reproduction of bone or arrest of the disease.

Dr. Webster related the case of a suicidal lunatic in Bethlem Hospital, who, in the year 1833, one day laid his head upon an open fire, then burning briskly. The hairy scalp and integuments were much injured; serious symptoms ensued, but life was saved, although the entire skull-cap exfoliated some months afterwards. He lived till September 1841; and at his death suffered from a hernia cerebri, the size of a hen's-egg, consisting principally of the posterior part of the left lobe. At the *post-mortem* examination, the vacuum, where the skull had exfoliated, was found filled up by a thick, dense, tough, and very firm structure, in which the dura mater and external cicatrix were inseparably blended. Dr. Webster also alluded to the remarkable case lately recorded in the *American Journal of the Medical Sciences*, in which recovery took place after an iron bar had been driven through the head.[1]

Mr. Shaw exhibited two specimens of extensive loss of the entire thickness of the calvarium, to show that the vacant spaces had been filled up in great measure by newly formed bone. One had been produced by scrofulous lupus twenty years before death, in a man fifty years old. No cerebral symptoms occurred till shortly before death, when he had hemiplegia from ramollissement of the right hemisphere of the brain near the corpus striatum. In the second case, the patient, a man about sixty years old, said that he had had a severe fracture of the skull forty-five years before, and that many large pieces had been removed by the surgeon.

Mr. Hodgson said, that in necrosis of the bones of the skull, there was only a slight deposit of bony matter. When a large portion of the skull was removed, the opening was filled up by fibro-cartilage, with a small portion of osseous matter in parts of it.

Treatment of Anasarca by Puncturing the Legs. By John Hilton, Esq., F.R.S. Experience had convinced the author of the great relief which anasarcous patients receive, when the fluid is allowed to escape through artificial openings; and that, when the operation is carefully performed, it is not usually followed by unfavourable results. The instrument recommended to be employed was a very narrow, sharp-pointed lancet. Two, or sometimes four punctures, should be made by it on the outer side of the thigh, by passing it obliquely through the subcutaneous areolar tissue, so as to reach, but not wound, the fascia covering the muscles. The limb or limbs should be wrapped separately in warm blankets, which should be often renewed, to prevent the limb from becoming cold or chilled. To prevent excoriation, when there was reason to apprehend this, capillary conductors should be used, in the form of worsted threads laid over the punctures, and passing into proper receptacles. By these means, the author believed that

[1] See London Journal of Medicine, September 1850, p. 893.

the external veins were allowed to become distended with blood, so as to relieve visceral congestion, and prevent effusion into the serous membranes.

Dr. C. J. B. Williams agreed with the author as to the advantages to be derived from puncturing the legs in anasarca. He thought, however, that the punctures afforded relief, not merely by getting rid of the superfluous serum, but by purifying the blood of those materials—especially urea—which were not removed by the excretory organs.

Fracture and Distortion of the Pelvis, with an unusual Form of Dislocation of the Femur. By Charles H. Moore, Esq. Case. J. F. H., a stone-sawyer, had been crushed, several years before death, beneath a piece of timber. At the age of sixty, he died of disease of the heart and kidneys, under the care of Dr. Seth Thompson, in the Middlesex Hospital. In addition to the immediately fatal disease, the bones were found thickened, heavy, course, rugged, and porous; the intervertebral substance was composed of alternations of calcareous matter and soft cartilage; the arteries almost everywhere, and the valves of the heart, were covered with calcareous matter. The left os innominatum was broken across the acetabulum, the right just in front of it; the ischio-pubal ramus was broken on each side. None of the fractures had united, though there were considerable portions of callus. The left bone remained in three fragments, corresponding almost precisely with its original segments; the right was broken in two. The head of the left femur had been driven between the fragments of the os innominatum into the pelvis, and lay only half an inch below the promontory of the sacrum. Its trochanter fitted into a shallow excavation on the outside of the ilium, and the joint was constituted by the thin edge of the ilium and the top of the shaft of the femur, close to the trochanter. A partial new socket had been formed by the expanded ends of the pubes and ischium. The body of the left ischium was displaced considerably inwards; but no material change had taken place subsequently to the injury, in the bones on that side of the pelvis. On the right side, the hip-joint was sound; and the shaft of the right femur was removed further from the centre of gravity than the left, by the whole length of its head and neck. Hence the spine had become curved forward and to the right in the lumbar and upper sacral regions; whilst the acetabulum, unsupported in front because of the ununited fractures of the pubes, had become elevated towards the depressed spine and promontory. The ilium had, partly from pressure, and partly from some softness, become bent above the sacro-sciatic notch; and the lateral mass of the sacrum had lost three-fourths of an inch of its natural breadth. The inlet, cavity, outlet, and sacro-sciatic notch on the right side were much narrowed, and the promontory of the sacrum was only one inch and a quarter distant from the pelvic surface of the right acetabulum. The ischium was pressed inwards and upwards, and encroached on the pelvis and the perinæum, and the symphysis pubis was thrust to the left of the mesial line.

Joseph Hodgson, Esq., F.R.S., President, in the Chair.

Relation of Sleep to Convulsive Affections. By W. F. Barlow, Esq. After noticing the frequent occurrence of convulsive affections during sleep, Mr. Barlow treated of the direct or predisposing causes of the convulsions, under the following heads. 1. The state of the circulation and respiration. 2. The condition of the motor force and muscular irritability. 3. The emotion of dreaming. 4. The withdrawal of the will. Dreaming had a very ample connexion with convulsions; and the causes of both had a most wide, though in great part indirect, relation. Great stress was laid on the withdrawal of the will. The inverse ratio of reflex movements, and of involuntary movements not reflex, to the power of volition, had not been duly applied to the solution of certain phenomena which occur during sleep.

The author referred to numerous experiments on man and the lower animals, by himself, Professor Volkmann, and Dr. Marshall Hall, which concurred to shew how often and how extremely a quiescent will tended to produce spasmodic affections. In convulsions, when the person was awake, there was not merely an evident, and sometimes successful, striving of the will. The author concluded by referring to certain motor local nervous affections—paralysis agitans, mercurial erethism, and chorea, which were wonderfully under the sway of slumber.

MEDICAL SOCIETY OF LONDON.

J. Risdon Bennett, M.D., President, in the Chair.

Diarrhœa as a hitherto unnoticed [?] Symptom of Menstruation: Use of Purgatives in the different Menstrual Epochs. By E. J. Tilt, M.D. Catamenial diarrhœa was examined with regard to its occurrence: 1. As a prodroma of menstruation: 2. During its regular establishment: 3. At its cessation.

1. As a prodroma of menstruation, diarrhœa scarcely ever occurs. 2. As a symptom of regularly-established menstruation, it occurred in 88 out of 161 cases. In these, it preceded the menstrual flow in 45; it accompanied it in 31; both preceded and accompanied it in 10; and in two instances habitually followed, not having preceded or accompanied it. 3. As a symptom of the cessation of the catamenia, diarrhœa was noticed in only 8 per cent. of the cases examined. The diarrhœa is usually unattended with pain, but sometimes nausea and slight colics precede for one or two days. When it appears at the change of life, it generally appears at irregular intervals. Dr. Tilt believed that the ovaries not only call the uterus into action, but also the nutritive organs, especially the intestines, which are under the influence of the same ganglionic nervous system.

With regard to purgatives during fully-established menstruation, Dr. Tilt would give them in defective menstruation, not dependent on serious organic lesion. Care should be taken, however, to give them at the time when the premonitory diarrhœa ought to occur, so as not to anticipate the catamenial period. In amenorrhœa and chlorosis, Dr. Tilt used an emeto-cathartic at the initial part of the treatment, followed by steel and bitters; but if there was not improvement, he put aside the steel and bitters, and repeated the emeto-cathartic.

After the cessation of menstruation, purgatives must be given habitually, to diminish plethora. The soap and aloes pill of the Pharmacopœia, in doses of five or ten grains, at dinner, was what Dr. Tilt frequently recommended. Flour of sulphur alone, or with sesquicarbonate or biborate of soda, and ipecacuanha, might be given in milk, to act mildly on the bowels.

Congenital Malformation of the Genito-Urinary Organs. Mr. T. H. Wakley exhibited a man suffering from malformed bladder, and stated that he proposed to try the effect of a plastic operation.

The New Superphosphate of Iron. Dr. Routh stated, in reference to the new preparation of iron he had brought before the Society on a former occasion, that it had been analysed and found to be a new salt—a superphosphate of iron dissolved in an excess of phosphoric acid. It was exceedingly pleasant to take, so that it was very well adapted for children. He believed it to be more speedy in its operation than many other preparations of iron. It had been now prepared in the form of a syrup by Mr. Greenish, of 20, New-street, Dorset-square; which is much cheaper than that of the iodide of iron.

Case of Spontaneous Collapse of the Antrum. By White Cooper, Esq. This paper appeared as an original article in the April number of this Journal.

Anniversary Meeting, March 8, 1851.

J. Risdon Bennett, M.D., President, in the Chair.

The seventy-ninth annual meeting was held at the Albion Tavern, Aldersgate-street. Dr. Rowland delivered the oration.

Election of Office-Bearers. President. E. W. Murphy, M.D. Vice-Presidents. J. F. Clarke, Esq.; F. Hird, Esq.; E. Lankester, M.D.; Forbes Winslow, M.D. Treasurer, H. Hancock, Esq. Librarian. W. A. Harrison, Esq. Secretaries in Ordinary. C. H. F. Routh, M.D.; C. Cogswell, M.D. Foreign Secretary. T. Davidson, M.D. Councillors. G. Pilcher, Esq.; E. Headland, Esq.; W. C. Dendy, Esq.; J. Middleton, Esq.; S. Stedman, Esq.; S. W. J. Merriman, M.D.; W. Smiles, M.D.; F. Sibson, M.D., F.R.S.; J. R. Bennett, M.D.; H. H. Walton, Esq.; J. Gay, Esq.; T. Nunn, Esq.; A. B. Garrod, M.D.; R. Druitt, Esq.; J. S. Bushnan, M.D.; W. Coulson, Esq.; J. W. Woodfall, M.D.; A. P. Stewart, M.D.; J. H. Bennet, M.D.; E. J. Tilt, M.D. Orator for 1852. Edwin Canton, Esq.

MISCELLANEOUS INTELLIGENCE.

Professor Kölliker. This distinguished histologist last autumn paid a scientific and recreative visit to Holland and Great Britain, in company with Dr. Czermak. From time to time, he expressed his opinions of what he saw, with regard to the subject which he particularly studies, in four letters, dated respectively from Utrecht, Leyden, Edinburgh, and London, and addressed to Dr. Von Siebold, his colleague in the editorship of the *Zeitschrift für wissenschaftlichen Zoologie.*

In Utrecht, he appears to have derived great pleasure from his examinations of the labours of Harting, Schroeder van der Kolk, and Donders; and he concludes his first letter by observing, that "Utrecht is a soil where science flourishes so vigorously, that no attempt should be made to transplant it without careful consideration". The letter from Leyden contains an account of his visit to that place and to Amsterdam.

From Holland, Drs. Kölliker and Czermak passed over to Edinburgh, and visited the Highlands, though, as the author says, not with much profit to science, especially as they had lost the opportunity of exploring the sea off the west coast in company with Forbes and Goodsir. On their return to Edinburgh, they spent ten days with Professor Goodsir, and visited the museums and schools of anatomy in that city. Of Professors Syme, Christison, and Simpson, Dr. Kölliker says:—"In the hospital, we less admired the safety than the ease and elegance with which Syme operates. The first is found in Germany; but the latter are more rare. . . . . Christison does all credit to the great name which he has in Germany; he is highly estimable as a man, and is, perhaps, next to Simpson, the most popular physician in Edinburgh. Simpson is incontestably the first obstetrician in Great Britain; he cannot have many equals, and perhaps no superior." The experiments of Dr. Simpson on parturition in swine, after removal of a portion of the spinal cord, are referred to by Dr. Kölliker, who says that, as far as they go, they show that parturition is independent of the action of the cord. In returning from a visit to the Bass Rock, the travellers were reminded, at the village of Whitechapel, twenty miles from Edinburgh, of the state of the study of anatomy in Britain, about twenty years ago, by the ponderous masses of iron trellis-work, which were used to protect the graves in the churchyard from the resurrectionists.

After a visit to Glasgow, Drs. Kölliker and Czermak proceeded to London:

and Dr. K. speaks in terms of great satisfaction of the reception which he met with from Mr. Quekett, of the Royal College of Surgeons. His collection of microscopic objects he believes to be in no way inferior to Harting's in Holland, but even to surpass it. W. Bowman, Sharpey, Todd, Wharton Jones, Carpenter, Owen, and Paget, receive each a justly deserved tribute. With regard to the Hunterian Museum, Dr. Kölliker thinks that it ought to be made much more available for instruction than it is at present. "So large an institution", he says, "should also be a large school" for anatomical instruction. The Regent's Park Zoological Gardens, the British Museum, and the Museum of Economic Geology, were each visited; and the hippopotamus is honoured with a brief notice.

Dr. Kölliker seems to have expressed his honest opinion of the state of anatomical knowledge in the places which he visited, and of the anatomists with whom he came in connexion. British *savants* and practitioners may well feel gratified and encouraged by the tribute which he pays to their industry and knowledge.

APPOINTMENTS.

Allen, Thomas, Esq., elected Assistant Medical Officer to the County Lunatic Asylum, Gloucester.

Bateman, Frederic, M.D., elected House-Surgeon to the Norfolk and Norwich Hospital.

Canton, Edwin, Esq., appointed Lecturer on Anatomy at Charing Cross Hospital, in the room of Francis Hird, Esq.

Chalmers, David, Esq., elected Honorary Assistant-Surgeon to the Northern Hospital, Liverpool.

Fletcher, E. A., Esq., Surgeon, elected Coroner of the Borough of Walsall.

Hird, Francis, Esq., appointed Lecturer on Physiology at Charing Cross Hospital, in the room of T. Wharton Jones, Esq., resigned.

Hooper, Dr. R. L., appointed Physician to the Surrey Dispensary, in the room of Dr. Birkett, resigned.

Jackson, Thomas Carr, Esq., appointed Assistant-Surgeon to the Royal Free Hospital.

Johnstone, Dr. James, Senior Physician to the General Hospital, Birmingham, appointed Joint Professor of Medicine in Queen's College.

Smith, Dr. Edward, appointed Lecturer on Botany at the Charing Cross Hospital.

Spence, Dr., appointed Assistant to the Superintendent of the Army Medical Department.

Wright, Dr. Samuel, Physician to the General Hospital, Birmingham, appointed Joint Professor of Therapeutics in Queen's College.

OBITUARY.

Smith, Henry, Esq., late of Torrington Square, at Kensington, on 18th April.

A MONTHLY

Record of the Medical Sciences.

JUNE 1851.—No. XXX.

ORIGINAL COMMUNICATIONS.

ON THE CAUSES, CONSEQUENCES, AND TREATMENT OF INFLAMMATION OF THE VEINS.

By HENRY LEE, Esq., F.R.C.S.Eng., Assistant-Surgeon to King's College Hospital, etc.

In the numbers of the London Journal of Medicine for March and July 1850,[1] I have attempted to establish the following points, in reference to the Pathology and Treatment of Inflammation of the Veins.

1st. That inflammation, both of the veins and of the capillary vessels, usually depends upon irritation, communicated to them through their contents.

2ndly. That pus is capable of producing such irritation when detained in contact with the lining membrane of the veins; but that it may be conveyed along their channels, without leaving any trace of its passage.

3rdly. That pus, under ordinary circumstances, cannot circulate in living vessels, in consequence of its power of determining the coagulation of the first portions of the blood with which it is brought in contact.

4thly. That when pus is carried along a vein, it is in consequence either of the disturbance of the coagulum which has first detained it, or of the blood having in some measure lost its natural power of coagulation.

5thly. That when, in consequence of either of these conditions, pus does find its way into the circulation, it may nevertheless determine the coagulation of the blood in its passage, either in a different part of the same vessel, or in distant parts of the system.

6thly. That when the coagulation occurs in a distant part of the body, it is usually observed in capillary vessels.

[1] Mr. Lee's valuable Essay has been published in a separate form by Mr. Renshaw. Ed. Lond. Journ. of Med.

7thly. That when it occurs in a large vein, it may affect the circulation through the whole of the vessels which supply it; and that if, for example, a coagulum be formed in, or extend to, the common iliac vein, the obstruction produced may give rise to all the symptoms of *phlegmasia dolens*.

8thly. That, under any of the circumstances above mentioned, bleeding and the use of mercurial medicines are of at least doubtful efficacy.

The evidence upon which these propositions are established it is unnecessary to recapitulate. It will rather be my object at present to review some of the labours of physiologists in connection with this subject, and to endeavour, by the assistance of the information derived from the action of foreign substances on the blood, to reconcile the discordant evidence which is found in their writings.

The direct action of foreign matter upon the blood opens an extensive and hitherto comparatively unexplored field of observation to the physiologist; while the admission of diseased secretions into the circulation affords an equally extensive and interesting sphere of study to the pathologist.

The direct effects of extraneous matters, when introduced into the circulation, may be divided into four principal classes, namely:—

I. Those which are occasioned by simple irritation as the foreign substance passes through the vessels.

II. Those which result from the particles of the matter introduced being of such a size, as to pass with difficulty through the small tubes, in which they consequently become entangled.

III. Those which are the result of the coagulation of the blood, determined by the presence of foreign matter.

IV. Those which depend upon a disposition communicated to the blood, to separate into its different parts, or to decompose.

I. Dr. Hales has left us the following experiment. He introduced a tube into the aorta of a living animal, and filled it with a column of water, which by its pressure would inject all the branches with a force supposed to be equal to that of the heart. He then cut a knuckle of intestine, so as to divide the small branches in the length of the intestine, on its free margin. The water from the tube was found to pass from the cut vessels in forty-six seconds, while, under the same circumstances, brandy took sixty-eight seconds before it found its way through the divided vessels. On a second trial, the brandy took seventy-two seconds in its transit.

By the same mode of experimenting, Dr. Hales found that warm water, of the temperature of the animal, passed much quicker than cold water from the pump. He thence concluded, that the contents of the vessels are capable of exciting them so as to contract their calibre, and to diminish the velocity with which fluids are circulated. Mechanical irritation may likewise, as proved by microscopical observation, cause the capillaries of a part to contract, so as to impede the flow of blood through them.

II. In the Museum of St. George's Hospital are preserved different portions of the femoral vein of a man, who was admitted into the hospital in consequence of a severe attack of erysipelas, which produced

several abscesses in the leg and thigh. "The femoral vein is filled with coagula of blood which had manifestly formed before death; and in some parts of the centre of the coagulum, there was found a light semi-fluid substance somewhat resembling pus, but which appeared to be only the dissolution of the coagulum."

It is evident, in such a case, that, whatever may have been the nature of the semi-fluid substance, it was retained in its position by the coagula which surrounded it; and had these been removed, it would then have had free access to the circulation. It is also more than probable that the particles, of which it was composed, were much larger than the blood corpuscles, and would consequently have met with a mechanical obstruction, had they been conveyed in the course of the circulation.

The following case illustrates the circumstance before insisted upon, viz.: the ready access that such vitiated fluids may have to the circulating system, when the coagulating power of the blood has, by disease or other causes, been impaired.

Case XLI.[1] Wm. Stubbs, æt. 30, of a swarthy complexion and emaciated appearance, was admitted into St. George's Hospital, Dec. 25, 1844. A year previously he had suffered from pain in the head and nausea. Three months before his admission, the pain in the head had become very severe, and was accompanied by frequent rigors, occasional vomiting, pain in the epigastrium, and region of the heart. The throbbing pain in the head was occasionally so severe, that he would frequently say that "all the disease was in the head".

He continued in the same state, with occasional rigors, till the 31st, when he vomited incessantly.

A soft pulpy tumor on the neck now attracted attention, which he said had existed since the beginning of October, when the previous symptoms had become so much aggravated. It was of the size of a small walnut, situated immediately over the carotid artery; pulsating, but not expanding with impulse.

He sank into the semi-comatose state, and died January 9th 1845.

This tumor,[2] upon examination, was found to be a small, perfectly circumscribed abscess, bounded on all sides by condensed cellular tissue. It contained a darkish coloured pus, and corresponded to the middle of the jugular vein. The cavity of the abscess here communicated with the vein by an opening of the size of a pea, and a probe could be passed through the opening into the cavity of the vessel. When first examined, the opening was partly blocked up by a thin coagulum. The internal coat of the vein presented its usual smooth and polished surface, and was but slightly discoloured, except in the neighbourhood of the opening. Here it was somewhat injected, and presented some yellow spots, apparently of pus, on the surface of the inner membrane. The outer covering of the vein was in this situation thickened and partially destroyed; the vein itself contained no blood.

A very small loose clot, presenting anything but the appearance of

[1] The Cases and Experiments are numbered in continuation of those related in my papers published in the London Journal of Medicine for March and July 1850.

[2] The *post-mortem* examination was conducted by Mr. P. Hewett.

blood, was found in the right auricle. It was of a brown rusty colour, mixed with streaks of a yellow hue. Examined by the microscope by Dr. Bence Jones, it was found to contain a remarkably small quantity of blood globules; but there existed a great number of large granular cells, the microscopic characters of which did not identify their nature.

It is remarkable in this case, that, although the contents of the abscess must from time to time have partially emptied themselves into the vein, yet, not being detained in it, they had excited little or no irritation.

The mode in which purulent fluid, when mixed with circulating blood, becomes altered in its characters, also deserves attention.

The coagulating power of the blood had evidently in this case been greatly impaired; and this circumstance can alone account for the ready admission which the pus gained to the circulation. On the other hand, how completely a coagulum will circumscribe purulent matter before the blood has lost its coagulating power, is illustrated by a case mentioned by Hunter,[1] in which an abscess formed in the substance of the left ventricle of the heart. "The inner wall of the abscess was formed, in this instance, by a solid coagulum of blood of an oval figure. This coagulum was of old standing, from its appearance, and was firmly entangled in the fasciculi of the ventricle."

Experiments illustrating the effects of the introduction of substances into the blood, which have afforded a mechanical impediment to the circulation, have been but too frequently repeated. The following are among those performed by M. Gaspard.

Experiment xxi. Half a drachm of liquid mercury, in half an ounce of common water, was injected into the saphena vein of a middling-sized dog. The animal, at first, experienced no inconvenience from the operation; but six hours afterwards the respiration became embarrassed, accompanied by fever, symptoms of pain in the chest, and disinclination for food. On the third day the animal appeared slightly relieved, and the appetite was returning when he was killed, fifty hours after the injection.

Post-mortem Appearances. Nearly the whole of the mercury was found to have lodged in the lungs, which were inflamed in hardened circumscribed patches, and in some places hepatised. The mercury escaped from the indurated tissue when it was divided.

Experiment xxii. Twenty-two grains of fluid mercury were injected into the jugular vein of a little dog by means of a glass tube. At the expiration of some days, there was a frequent dry cough, with occasional shiverings.

Post-mortem Appearances. The mercury was found, after death, in the lungs, which were inflamed in indurated patches in different parts.

Experiment xxiii. Twenty-two grains of mercury were injected into the jugular vein of a large dog.

Post-mortem Appearances. Four days afterwards, the mercury was found detained in the lungs, in about thirty inflamed spots of induration, varying in size from a pea to a filbert. In some of these suppuration had commenced.

Experiment xxiv. Two drachms of mercury were introduced into the jugular vein of a very large dog. Six hours afterwards, the animal

[1] Pathological Catalogue of Coll. of Surg., vol. ii, p. 4, from M.S. Cat.

refused his food, became feverish, and presented the usual symptoms of inflammation of the lungs; subsequently he appeared better, the appetite returned, and a very frequent cough was the only remaining prominent symptom. On the ninth day, a number of globules appeared in the fecal matter, and continued to pass till the thirteenth day, after which they disappeared. The animal's health was now in some measure restored, when he was killed.

Post-mortem Appearances. The lungs were found much altered by inflammation, adherent to the pleura, and solidified; they contained a great number of indurated tumours, filled with pus and mercury. No mercury was found in the other organs, with the exception of a few grains in the pleura, and in the liver. The stomach and the intestines contained a considerable quantity, but none could be detected in the vessels of those parts; some was, however, met with in the œsophagus, in the trachea, and in the bronchi. These last also contained some *débris* of the pulmonary tissue. The presence of the mercury in the liver is attributed by M. Gaspard, in this case, to its having regurgitated from the right cavity of the heart into the inferior vena cava, and having thence gravitated into the venæ cavæ hepaticæ.

These experiments are in accordance with that of Clayton, who, having injected mercury into the jugular vein, found it again four months afterwards in an abscess in the lung.

From all these cases it appears, that liquid mercury cannot circulate in the living vessels, because it becomes mechanically stopped in the capillary system of the lungs, where it impedes the circulation, and causes inflammation and suppuration. It has been asserted, that the abscesses thus found differ in their characters from secondary abscesses, arising from purulent infection. The difference, however, as we shall hereafter see, arises simply from the fact of a larger number of capillaries being obstructed at once (in consequence of the tendency of the blood to coagulate) in the latter than in the former case.

Experiments Nos. XVI and XVII, before recited,[1] show that where mercury is introduced through one of the branches of the aorta, the terminal vessels are affected in the same way as when it is carried along the pulmonary artery. The first system of capillaries to which the foreign matter is sent, is that in which, and in which alone, in these instances, the inflammatory symptoms are developed.

The same principle may be illustrated with regard to the portal circulation. If fluid mercury is injected into one of the mesenteric veins, it is arrested in its progress in the capillary system of the liver, where each globule of mercury becomes the centre of a small patch of congestion, which terminates in suppuration. In all the cases now mentioned, it certainly does not appear to be the size of the globules which prevents the passage of the fluid through the capillary tubes; for, even in the dead body, these may be perfectly injected with mercury. Another explanation must therefore be sought for, and one presents itself which appears to throw considerable light upon this question. If fluid mercury be agitated with recently drawn blood, it will have little effect in coagulating it *en masse*, but some of

[1] London Journal of Medicine, March 1850, vol. ii, pp. 237-8.

the globules of the mercury become very firmly attached to small portions of fibrine, and the two will be found to adhere very firmly together. In this experiment, the fibrine of the blood is no doubt separated to a certain extent from its other parts (as it would be if beaten with a twig), and adheres to the foreign substance with which it is brought in contact. May we not suppose that something of the same kind takes place in the living vessels,—that, as the globules of mercury are shaken with the blood, the latter parts with some of its fibrine, which adhering to the former, prevents it from being carried forward in the course of circulation?

Impalpable powders, when suspended in water and introduced into the blood, are likewise mechanically arrested by the first capillary system to which they are sent. Oily and viscid fluids, as illustrated in the following experiments, are also unable to pass through the minute tubes of the different organs of the body.

Experiment xxiv. A full half-ounce of chicken's fat, refined and melted, was injected into the jugular vein of a very large dog. The animal was immediately affected with extreme dyspnœa, faintness, and prostration of strength, accompanied by a very slow pulse and inability to stand. An hour afterwards, there were fever, shiverings, symptoms of pain in the chest, and a frequent pulse. These symptoms continued during the second day; and on the third, the animal was enabled to get up and to walk, although with a very unsteady motion. On the second day, the excrements were soft, yellow, pultaceous, and oily; similar evacuations also occurred on the fourth day, after which they were not observed. On the sixth day, the animal was convalescent.

Experiment xxv. Some mercurial ointment was injected two days afterwards into the opposite jugular vein of the same dog; the quantity employed was about a fourth part of that used in the last experiment. There was immediate prostration of strength; the body was rendered immoveable, and the pulse was reduced to twenty-four beats in the minute. The respiration became very slow and short. An hour afterwards, the pulse rose to thirty, and the respiration became more free. Extreme dyspnœa, however, followed, and the animal died an hour and a half after the injection of the ointment.

Post-mortem Apprearances. The lungs were found inflamed and hepatised from the former experiment. The branches of the pulmonary artery were obstructed with a dark concrete fibrous and elastic clot. This had moulded itself to the branches of the pulmonary artery, and followed its ramifications.

Experiment xxvi. Three drachms of olive oil, warmed, were injected into the jugular vein of a fox. As in the former experiments, there was complete loss of power; the respiration was interfered with, and the pulse faltered. The animal died at the expiration of twenty minutes.

Post-mortem Appearances. The body was examined four hours afterwards. Some bloody fluid was contained in the bronchi; the venous system, the right cavities of the heart, and the lungs, were greatly gorged with blood. The pulmonary tissue, for the most part, no longer crepitated upon pressure, and portions of it sank when

placed in water. Some drops of oil could be distinguished exuding from its structure, which left an oily feeling upon the fingers.

A considerable difference of opinion appears to have existed respecting the effect of the introduction of milk into the veins. Hunter found that the injection of milk into the veins of a dog proved fatal; while M. Gaspard affirms that as much as six drachms may be made to pass into the circulation, without in any way interfering with the animal functions. In trying the effect of milk upon recently-drawn blood, I find that, if the milk is fresh, it tends to retard the coagulation of the blood; but if it is sour, it promotes it in a very marked degree. It is not improbable, that this circumstance may account for the different effects which have been observed by different physiologists upon this point, and may reconcile the discordant evidence which they have left us.

Experiment xxvii. A grain and a half of corrosive sublimate, dissolved in water, were injected into the veins of a middling-sized bitch. This was followed by a kind of dysentery, and vomiting of sanious jelly-like matter. From time to time, there was great increase in the secretion of saliva; symptoms of inflammation of the lungs supervened, and death occurred three days afterwards.

Post-mortem Appearances. On opening the body, the rectum was found much inflamed, the liver dark-coloured, and the gall-bladder full of thick viscid black bile. The lungs were studded with a number of little abscesses, separated from each other by nearly healthy pulmonary tissue.

Experiment xxviii. A grain of corrosive sublimate introduced into the jugular vein was soon followed by increased secretion of saliva, dyspnœa, and symptoms of inflammation of the lungs. Death occurred on the fourth day.

Post-mortem Appearances. Scattered through the lungs were found very dark tumours, varying in size from a pea to a filbert. Some of these were inflamed, some had suppurated, while others were gangrenous. The liver was dark, and soft in structure; the gall-bladder full of black, thick, and viscid bile.

In repeating this experiment with five grains of the salt, dissolved in an ounce and of half a distilled water, the animal died in a few seconds.

In these last experiments, we find that the foreign matter is not confined in its influence to the first system of capillaries to which it is conveyed. There is a disposition manifested to expend its morbid action on the liver and the mucous membrane of the intestines—a disposition which we shall find still farther developed in the fourth class of cases above mentioned.

(To be continued.)

ON THE PATHOLOGY AND TREATMENT OF PUERPERAL INSANITY:

ESPECIALLY IN REFERENCE TO ITS RELATION TO ANÆMIA.

By F. W. MACKENZIE, M.D., Physician to the Paddington Free Dispensary for the Diseases of Women and Children, Fellow of University College, etc.

THE pathology of Puerperal Insanity, and its relation to morbid conditions of the organism, are still involved in much obscurity, notwithstanding all that has been written upon the subject. Indeed, on referring to the writings of the most eminent obstetricians, it will be found that much diversity of opinion prevails in regard to it; and it would be as difficult to deduce from them a satisfactory theory of the disease, as a sound and efficient system of treatment. It must, however, be admitted, that many difficulties present themselves in the investigation of the subject, independently of such as are of a metaphysical nature. In many cases, the advent of the disease is so sudden, and its effects upon the sensorial functions so marked, that the patient is rapidly bereft of reason, and with it, of the power of expressing her feelings, or the causes which may have led to the attack. It frequently happens, that the obstetric attendant is called upon to attend his parturient patient without any knowledge of her previous state of health or predisposition to disease, and thus is unable to appreciate the circumstances, which may have remotely and principally led to the attack. Lastly, in regard to the malady in question, it is admitted that any individual experience must be limited, and therefore not such as to justify very sweeping conclusions, either as to its origin, pathology, or treatment.

From these and other causes which might be mentioned, there is often much difficulty in arriving at correct views respecting the nature of this disease, and the writings of even acknowledged authorities contain very contradictory doctrines in regard to it. It has been attributed, for instance, "to the suppression of the lochia"; to a "metastasis of the milk"; to a "peculiar condition of the sexual system which occurs after delivery"; to "local irritation of the mammæ, uterus, and other parts"; to the "disturbances of the vascular system occasioned by delivery"; to the "combined effects of irritation and loss of blood"; to "nervous irritability and excitement", etc. These circumstances, however, would appear to give a too partial explanation of its origin; for whilst they are almost constant and universal in their operation, the disease in question is admitted to be comparatively rare.

On the other hand, that some special predisposition must exist in those who are attacked by it, is, I think, sufficiently certain from a variety of circumstances. Its occurrence, as has been stated, is comparatively rare. The causes which ordinarily induce it, will, in many instances, fail to do so; and it is often met with, without the intervention of any applicable exciting causes. Now the circumstances in which this predisposition originates, would appear to have been but little attended to. Hereditary tendencies and a highly nervous temperament have been recognised as the most important; and most writers agree in connecting it with an adynamic state of the constitution. This view was

especially enforced by Dr. Gooch, to whom we are indebted for a most philosophical essay upon the subject, and who may be said to have been the first to delineate clearly the real character of the disease; but we have still to be informed of the causes of this adynamia. Where hæmorrhage has occurred subsequently to labour, or blood-letting has been practised, as also where long-continued suckling has preceded the attack, the causes of it are sufficiently obvious; but it is met with in many instances irrespectively of these, and, indeed, in the absence of any exciting cause whatever. To what then is it attributable? I have made many inquiries on the subject, and they lead me to believe that in these, and indeed in the majority of cases in which puerperal insanity occurs, it is mainly dependent upon the existence of anæmia antecedently to labour. In every case which I have attended, such an inference has been clearly deducible from the history; and on looking to the published cases of others, this opinion is supported, if not confirmed. I propose, therefore, to draw attention to this point in the present paper, and to inquire how far such an opinion is verifiable, and in accordance with well-ascertained facts.

It is unquestionably a fact, that anæmia, in various degrees, prevails very generally amongst females, and that its existence is often unrecognised both by the patient and her friends; whilst, at the same time, its influence is very considerable in modifying and predisposing to various secondary diseases. The great susceptibility of the nervous system in females generally, both consequent upon, and independently of, impregnation and its results, is well known; but its connexion with certain conditions of the blood does not appear to have been as fully appreciated. It has been observed, for instance, that the nervous system of the female in health is far more irritable and susceptible to impression than that of the male; but it is also the case, that the healthy constitution of the blood of the former differs materially from that of the latter, and that, with a slight exception in favour of albumen, the blood of the female contains a smaller proportion of nutritive and vivifying elements than that of the male.[1]

The avocations of females in many instances, their education and modes of life, more especially of those of the upper classes of society, doubtless tend still further to diminish this proportion, and to produce a correspondingly more irritable condition of the nervous system, as well as a greater susceptibility to the operation of disturbing causes. Anæmia, however, when slowly induced, and existing even in an extreme degree, is not incompatible with a comparatively healthy performance of the bodily functions, and thus may have been of long continuance without attracting any particular notice; but persons so

[1] I subjoin the following table from Dr. Carpenter's Physiology, embodying the general results of the analysis of Denis on this point.

	Male.		Female.	
	Maximum.	Minimum.	Maximum.	Minimum.
Water	805	732	848	753
Albumen....	63	48·5	68	50
Globules....	186	110·5	167	71·4
Fibrin	4	2	3·1	2

suffering readily succumb to morbid influences; they are unequal to much fatigue, possess, for the most part, but little energy, and are often incapable of performing their allotted and ordinary duties. Should impregnation take place under these circumstances, the blood becomes still further impoverished, and the constitutional powers heavily taxed in the performance of the functions necessary for the purpose of "forming, lodging, expelling, and feeding the offspring." If secondary disease has hitherto been averted, there is now a greater probability of its supervening, and hence, during utero-gestation, various functional disorders are liable to occur. The brain and nervous system in particular become unduly excitable, and, in some cases, incapable of withstanding the shock and the consequences of labour. Hence it is, that intense cerebral disturbance, consequent upon great nervous irritability, is so liable to occur under such circumstances, with or without the supervention of some casual exciting cause.

On reviewing the symptoms which ordinarily characterise an attack of puerperal insanity, we see nothing that is inconsistent with the view which has been expressed. The progress and termination of the malady do not militate against it, nor do the *post-mortem* appearances in such cases as have terminated fatally. I shall briefly refer to each of these points, as elucidating the pathology of the disease; and commence with the symptoms, which I shall cursorily describe as they have presented themselves to me in practice.

Symptoms. When mania occurs during the puerperal state, its accession is in some instances sudden, as where some violent mental emotion has been the exciting cause; but more frequently it is otherwise, and it is ushered in by certain premonitory symptoms. Of these, one of the most frequent is restlessness or sleeplessness at night, a symptom which almost invariably precedes the full development of the disease. The patient at the same time is often excitable during the day, and evinces some peculiarity or other. She may express herself as feeling unusually happy, or otherwise; there may be a degree of vivacity about her which is unaccustomed; or, on the other hand, she may be excessively reserved. One patient will be constantly talking, while another will be sullen and taciturn, and there is often some strange fancy or idea upon which she more particularly dwells. The pulse at this time is generally quick; but it is weak and easy of compression, and although the head may be hot and the countenance flushed, the extremities, and especially the feet and hands, are either cold or below the average temperature. Up to this period, the patient appears to be rather eccentric than mad; she is easily managed, and readily does what she is advised; but after a time she becomes more positive, more impatient of contradiction, and at length violent and unruly. Her nights are now passed without any sleep, her countenance is flushed and excited, her head hot, and her eyes suffused. The tongue is mostly furred and dry, but it may be clean or covered with a slimy mucus; the breath is often offensive, more especially in the morning; the bowels are torpid, the stools unhealthy, and the urine scanty. With the development of these symptoms the delirium rapidly increases, and the case, so far as the cerebral disorder is concerned, presents very little difference from that of ordinary mania. The state of the circu-

lation is, however, still peculiar; the pulse continues weak, though quick; the extremities are cold and clammy; the inner lips are pallid; and the patient, unless under the excitement of delirium, appears to suffer from extreme prostration.

These symptoms, it will be observed, do not materially differ from the cerebral disorders which are sometimes met with in anæmiated persons, when causes of sufficient intensity disturb the sensorial functions; and although such cases must have occurred in the experience of most practitioners, I will briefly quote the following in illustration.

Case. On the 23rd of November 1843, I visited Elizabeth Waugh, a girl aged 14, who, shortly after receiving a fright, had exhibited symptoms of excitement and cerebral disturbance. She had been delirious for some days before I saw her, and had been under the care of a practitioner, who, in consequence of the heat of head, flushing of the face, quick pulse, and the delirious state of the patient, had treated the case as one of mild phrenitis. The head had been shaved, cold lotions applied, and purgatives and antimonials administered. Under this treatment, however, the symptoms rather increased than lessened in severity; and on visiting her, I found her suffering from many of those which I have mentioned as occurring in puerperal mania. The pulse indeed was quick, but very weak; the head was hot, but the extremities were cold; the face was flushed, but the inner lips were pallid, and there was evidently much physical prostration, whatever might be the nature of the cerebral disorder. These circumstances, together with the effect of the past treatment, led me to consider whether the case might not be one of irritation rather than of inflammation, and her previous history left no doubt on my mind as to its being so. She had been a remarkably weakly, ailing child from infancy; had lost her father and mother at an early age, and at one time had been so destitute, and so little provided for, that she had been placed temporarily in an asylum by a clergyman; she had left this some months before the present attack commenced, but it was observed by those who had the charge of her, that she had been, previously to leaving, very weak and pale, and incapable of undergoing fatigue. With this history, looking to the patient's general symptoms, and discovering a loud venous bruit in the neck, I did not hesitate to order a nutritious diet, and a moderate allowance of wine. The bowels were attended to, and the medicine specially prescribed was the carbonate of iron in rather full doses. Upon this treatment, in a week, she was much better; by the 7th of December she was convalescent; and on the 23rd I left her, not only cured of the cerebral affection, but much better in health than she had been for some time.

This case was in no respect dissimilar to those which I have seen of puerperal mania; in the latter, there has always been great cerebral excitement conjoined with much physical exhaustion, and for this there is often no sufficient cause to be found, either in the labour itself, or the circumstances which have followed it. If, however, the history of such cases be carefully investigated, the practitioner will generally find that anæmia, often in a marked form, had existed antecedently to labour.

The progress and termination of the puerperal attack vary in different cases. It may terminate in spontaneous recovery, a result

which will be hastened by judicious treatment. It may be followed by protracted insanity of many months or years duration; and in some instances it has terminated fatally. When such has been the case, the *post-mortem* appearances have been generally of a negative character as regards the existence of any active cerebral disease. Dr. Copland observes, "that those caused by pure or true puerperal insanity, particularly where it occurs soon after delivery, or during suckling, consist chiefly of deficiency of blood in the brain and its membranes; and in some instances, of slight effusions of serum between the membranes and in the ventricles. There are no signs of inflammation, or even of congestion, excepting in such cases as have approached in their character to phrenitis, on the one hand, or to nervous fever on the other. The pure cases of the malady present little beside anæmia of the brain and its membranes, and of the system generally."[1]

Dr. Gooch observed the following appearances in a case which terminated fatally. "The veins throughout the body were remarkably empty; the heart contained little blood; the lungs and liver were singularly pale; within the head there was the same deficiency of blood in the veins of the pia mater and in the sinuses; under the arachnoid there was a little serum; and, on slicing off the hemisphere, the bloody points were unusually numerous." Such appearances are probably those which would be met with in recent cases; but where the attack has been protracted or has merged into settled insanity, various organic changes will doubtless be found; indeed, the statistics of lunatic asylums show, that almost every form of organic lesion has been met with in the brain and its membranes in such protracted cases. These, however, are probably the consequence of secondary disease, or of the long continuance of great functional disorder.

But neither a fatal termination, nor evidence of congestion of the brain, with more or less serous effusion into the ventricles, or between the membranes after death, would render the opinion which has been expressed as to the origin of the disease either improbable or incorrect. Simple cases of anæmia, uncomplicated with the circumstances of the puerperal state, have terminated fatally after symptoms of great mental and cerebral excitement, and appearances similar to those stated have been found after death, when there was no evidence of the existence of inflammation during life.

Dr. C. J. B. Williams observes; "I have met with several cases more or less corresponding with the following description. A young female becomes anæmic, and after exhibiting various symptoms of feeble general circulation, with headache, drowsiness, and impaired sensorial functions, suddenly becomes worse; passes into a state of stupor, with dilated pupils, sometimes varied by slight *manifestations of delirium*, throbbing of the carotids, and partial heat of the head, and dies comatose.

"On opening the head, a small quantity of serum is found under the arachnoid, and in the ventricles, sometimes with a little lymph (in one case there was none). The vascularity of the membranes is remarkable; but the vessels most distended are the veins; and in the larger of these, and in the longitudinal sinus there is a firm coagulum. In

[1] Copland in Dictionary of Practical Medicine, Part vii, p. 547.

parts, especially at the torcular Herophili, this coagulum blocks the whole sinus, and exhibits a separation of fibrine; portions of which are softened down into that opaque purilaginous matter, which was long mistaken for pus, but which Mr. Gulliver has shown to be a mere disintegration of the fibrin, which mere stagnation, in a warm temperature, may effect. These have been taken for cases of meningitis. No doubt, inflammation may supervene in them occasionally; but in two cases, which have fallen under my notice, there was no adhesion of the arachnoid, nor deposit upon it, nor any other unequivocal mark of inflammatory action. Yet the fibrinous and bloody concretions in the veins and sinuses were most remarkable for their size and firmness. It appears to me most probable that these affections originate in the encephalic congestion connected with anæmia".[1]

In the foregoing description of the symptoms, I have not attempted to delineate the disease in all its several phases, or to indicate more than, very generally, its leading features and symptoms as I have most frequently met with it in practice. To enter into such details would answer no useful purpose, for in no two instances would the same train of symptoms be observed. It will present differences in individual cases according to the general state of the patient, the causes which have immediately excited it, and the temperament and peculiarities of the patient. In some instances the insanity will be attended with despondency, in others with hilarity, and it may vary from a mere hallucination upon a single point, to the most complete perversion of all thought and reason.

Pathology. A far more important question is involved in the consideration of the nature and pathology of the disease, and the determination of the physical condition upon which it principally depends. I have expressed the opinion that its origin is intimately connected with a defective condition of the blood; and this view, which has been suggested by the cases which I have attended, is strengthened by the histories of those which have been published by others. I would particularly refer to the paper of Dr. Gooch, on the "Disorders of the Mind in Lying-in Women"; in corroboration, to the cases which he has reported, and the inferences which he has drawn from them. After giving a careful history of them in detail, he adds a summary of them in the following words:—"What inferences are we to draw from the foregoing cases relative to the question, for the solution of which I have related them; viz., what is the morbid condition of organisation on which puerperal insanity depends? Let the reader reflect on the leading point in these cases. In No. 1 the disease occurred in a *pale lady, without any heat of skin*, or much quickness of pulse, and was not relieved by the loss of blood. In No. 3 it occurred in one whose constitution *was drained and enfeebled by nursing*. In No. 4 it occurred in a *pale* woman, habitually hysterical, subject to bear dead children *from want of power to afford them life* for nine months. In No. 5 it occurred in one who had *been drained by flooding*. In No. 6, in one whom, for urgent reasons, the *circulation had been reduced to the lowest ebb consistent with life*. In No. 7, in one who had been *living very low for a week*, with such marked symptoms of the irritation of debility,

[1] Williams (C. J. B., M.D.) Principles of Medicine. Second Edition, pp. 167-8.

that at first sight I thought it was the close of some disease that had been overlooked. It was speedily relieved; not by cupping and purging, but by the tranquillizing and sustaining power of opium. In No. 8 the disease was treated, though with all possible prudence and moderation, as an inflammatory state of the brain, by leeches, cupping, purging, and low diet, yet the patient died; not with symptoms of oppressed brain, but with those of exhaustion; and on examining the body, the whole venous system was found *extraordinarily empty of blood*. In No. 10 the patient fell, as if shot, under the stroke of the lancet; and, on examining the head, there was found no effusion, and *empty blood-vessels*. In No. 11 the disease came on after puerperal convulsions; a disease generally, but not always, depending on cerebral congestion; and after *one of those enormous bleedings*, commonly practised in these cases, and no morbid appearances were discovered after death in the brain".

Dr. Gooch then observes: "These cases, if fair specimens of puerperal insanity, lead straight to the conclusion, that the disease is not one of congestion or inflammation, but one of excitement without power".[1] Of the correctness of this conclusion there cannot, I apprehend, be a doubt. As far as it goes, it expresses fully the fact, but it leaves the principal difficulty unexplained. It fails to inform us of the circumstances upon which this excitement without power depends, and thus to enlighten us upon the real nature of the disease. It is clear, however, that another conclusion may be drawn from these cases. In all, the patients were more or less anæmiated prior to the attack. In some, this had followed hæmorrhage or blood-letting, but in others it was irrespective of either, and had probably existed long antecedently to labour.

The cases more recently reported by Drs. McClintock and Hardy, in their valuable work on *Midwifery and the Diseases incident to the Puerperal State*, are of the same general character, and justify a similar conclusion. The cases published by them amount altogether to six; of these, the attack followed blood-letting in four; in one it occurred in a person who had been living in a state of extreme destitution previously to her labour; and in the sixth it followed diarrhœa. In the following summary the principal facts of these cases are stated, so far as they bear upon the question under consideration.

In No. 1, the patient went on well until the fifth day after her labour, when she was bled on account of cough; on the sixth day the bleeding was repeated, and at nine o'clock, P.M., of the same day, she awoke screaming, and quite maniacal. The cerebral excitement was tranquillized by tartar emetic; but she subsequently became so weak and low that stimulants were necessary. After this she was attacked with erysipelas on the side of the head and face, and eventually died. A post-mortem examination revealed vascularity of the arachnoid, and about an ounce and a half of serum at the base of the brain. In No. 2, it occurred after bleeding for pain in the uterine region. The attack commenced on the evening of the same day of the bleeding; but it readily yielded to tartar emetic treatment. In No. 3, the patient fainted twice during labour. On the third day she was bled. This occasioned

[1] Gooch, Dr. Diseases Peculiar to Women, Second Edition, pp. 139, 140.

a feeling of faintness, and was followed by mental disturbance. In No. 4, the patient was bled upon the second day after delivery, mania occurred on the fifth, and on the eighth it was very intense, but it was treated successfully with tartar emetic. In No. 5, the patient was an unfortunate woman who had been abandoned by her husband, and who, when admitted, was in a state of extreme poverty and destitution. In No. 6, the attack followed diarrhœa, for which low diet was ordered; it commenced about five days subsequently; the stomach and bowels were greatly disordered, but the patient eventually did well.

As I have already observed, the general character of these cases does not materially differ from those related by Dr. Gooch. In the fifth case, the patient could not have been otherwise than anæmiated previously to her labour. In the sixth case, the patient was in a state of extreme prostration before the attack commenced; and, judging from the results of bleeding in the four first, it is scarcely likely that any of the patients could have been in ordinary health before the commencement of labour. At all events, mania is not a usual consequence of blood-letting, when properly practised; and when depletion is followed by such a result, it at least justifies this inference, that whatever may have been the symptoms for which it was performed, the patients were more or less anæmiated prior to its performance.

A case is reported by Abercrombie under the head "Meningitis", in his work on the *Diseases of the Brain and Spinal Cord*, so much to the present purpose that I subjoin the following particulars of it. "A lady, aged 38, was recovering from her eleventh accouchement, when, for some local affection, repeated topical bleeding was practised. This, with other remedies, subdued her febrile symptoms; but after three or four weeks she was still confined to her bed, and considerably reduced in strength. At this time, she became one day alarmed and agitated by some family occurrence, and immediately began to talk wildly and incoherently, and, after a restless night, was found next day in a state of the highest excitement, talking incessantly, screaming and struggling, with a wild expression of countenance, and a small rapid pulse. She was treated by topical bleeding, laxatives, cold applications to the head, etc., but with little or no benefit; and on visiting her on the following day I found her sitting up in bed, with a look of extreme wildness; both her hands in constant motion, talking incessantly and wildly; and I learnt that she had not ceased talking for one instant for the last twelve hours. Her pulse was now rapid and feeble, and her countenance expressive of exhaustion. In consultation with a highly intelligent friend, who had charge of the case, I mentioned my experience of the fatal nature of the affection, and proposed to make trial of treatment by stimulants. A glass of wine was accordingly given, with evident abatement of the symptoms, and it was ordered to be repeated every hour. At the end of the fourth hour she was perfectly composed and rational, her pulse about 90, and of good strength, and from this time there was no return of the symptoms".[1] The state of health of this patient, antecedently to labour, is not mentioned; but the fact of her having had ten children previously,

[1] Abercrombie (John, M.D.) Pathological and Practical Researches on Diseases of the Brain and Spinal Cord, pp. 64-65.

would, I think, tend to show that her constitution and blood had been somewhat impaired; for nothing induces anæmia in females more certainly than having children very rapidly, and more especially when all are suckled by the mother. In this case anæmia had probably predisposed to the attack, in conjunction with the local blood-letting; this, however, does not appear to have been carried to any great extent, and, in a person not otherwise anæmiated, would scarcely have produced a state of constitution so favourable to the development of mental disorder.

The cases which have come under my own observation have appeared to be essentially similar to those related, and to have originated remotely, and principally, in a defective condition of the blood. In all, anæmia had existed concurrently with the attack, as well as antecedently to it. In one patient, with whose previous history I was well acquainted, it had existed during the greater part of pregnancy, and was probably the sole cause of the mania. In another it was apparent when the patient was suffering from the malady, which disappeared under treatment calculated to improve the general health. But it reappeared some months subsequently, not as the effect of child-bearing or its consequences, but as the result of a return of bad health, and an impoverished state of the blood. Many cases of this form of mania have been admitted, during the last three years, into the Paddington Infirmary, in females who had been suckling their children under circumstances of much privation; in all of them, anæmia existed in a marked manner, and the intensity of the cerebral disorder, as well as the danger, was found to be proportionate to the degree in which the blood had been impoverished. I shall subjoin the particulars of some which I have attended.

Case. The first I shall refer to is instructive, as showing the extreme intolerance of blood-letting in these cases, and is otherwise corroborative of the views which I have expressed. In November 1845, I went to Fulham to see a lady who had become deranged a few days after her confinement; but before I saw her she had been bled rather largely, on account, as her medical attendant stated, of her extreme excitement; *this, however, instead of having been lessened by the bleeding, had been much increased by it.* I found her sitting up in bed, raving incessantly, and she had been so for many hours. Her head was very hot, and her face suffused, but her inner lips were pale, her pulse weak and quick; the feet and hands cool, and the skin moist. No cause could be assigned for the attack. She had an easy labour, and it was neither attended by hæmorrhage nor any thing unusual. She had not experienced any mental shock or uneasiness subsequently; nor did the state of the tongue, or any thing else, indicate gastro-intestinal irritation. It was, however, evident that she was very much anæmiated, and her history clearly showed that anæmia had existed prior to labour. She had a very large family. She had suckled each of her children an unusual period; and the constant strain upon her constitution, induced by pregnancy and lactation, had evidently given rise to this insufficiency of blood. Sustaining and tranquillizing treatment was recommended; but the case was considered by her husband and friends to be so bad, that she was shortly removed to an asylum. I visited her there some weeks afterwards, but she was not then materially

better, and many months elapsed before she was deemed sufficiently convalescent to return to her family. I cannot doubt that this protracted convalescence was mainly attributable to blood-letting after the accession of the maniacal symptoms.

Case. In another case, the patient was attended by myself in labour, in Dec. 1843. This took place prematurely, and the child was still-born. No hæmorrhage occurred subsequently, or anything unusual, nor had she experienced any shock or mental emotion; and for a few days she appeared to be doing as well as it was possible. I had never attended her before this labour, and I knew nothing of her previous state of health; but she did not appear to be strong. She was pale and emaciated; and the labour appeared to have taken place prematurely as the result of bad health. Four days after her confinement she became delirious; and I found her talking very incoherently, and impressed with the idea that people were about her, endeavouring to destroy her. She had a wild unsettled look; her countenance was flushed, and her eyes suffused; her pulse was small and quick, and her extremities cool. No cause could be assigned for the attack, either mental or otherwise. Her tongue was clean, and her bowels had been regularly relieved.

The immediate treatment consisted in giving sixty drops of the tincture of henbane, applying ice to the head, and occasionally administering light nourishing food. A second dose of henbane was given, two hours after the first; and this procured some sleep, and she awoke more composed. On subsequently inquiring into the history of the case, the following particulars were elicited.

The patient had enjoyed good health, until five years previously. She then lost her mother; and, in consequence, suffered much mental distress and excitement. Nervous symptoms came on, which were supposed to arise from brain-fever; and she was in consequence very much lowered, and had a considerable quantity of blood abstracted. This treatment gave rise to increased nervous excitement, and also to mental derangement, which continued for some months; and ever since, she had been nervous and excitable. Such a history clearly pointed to the existence of anæmia, as a consequence of the lowering treatment and depletion; and I found, on examination, the indications of it in a decided form. There was a loud bruit over the veins of the neck; the inner surface of the lips was pale, as was also that of the eyelids; the pulse was weak, and her whole appearance indicated great deficiency of blood. The treatment adopted had reference to this, and to tranquillizing the nervous system. A nutritive diet was enjoined, with the moderate exhibition of steel, and occasional aperients: sedatives were given at bedtime, when restless or indisposed for sleep. Her general health improved; and in a fortnight she was convalescent.

A twelvemonth subsequently to this, I had again to see this patient, in consequence of symptoms of returning insanity; and I found her labouring under marked delusions. She was not now pregnant, neither had she been suckling; nor had any cause connected with child-bearing been in operation: nevertheless, it was evident that her intellect was disordered. She entertained strange and unfounded apprehensions, had sleepless nights, and many of the symptoms which had

characterised her previous attack of puerperal insanity. The only explanation which could be found for this, was the state of her general health, which had again become impaired. There was evidently anæmia, and with it a disordered condition of the stomach and digestive organs. These circumstances alone appeared to have given rise to the present attack; and it speedily disappeared on correcting them. Two years subsequently to this, she gave birth to a fine healthy child, which she suckled for some time, without any return of mental disorder.

For some years after this, she continued in the enjoyment of excellent health, mainly by taking great care, regular exercise, and attending rigidly to diet and regimen. Only six weeks ago, however, I was again consulted by her, on account of weakness and nervous symptoms. She passed sleepless nights, and had various odd and unnatural feelings. These I found to have been preceded, and to be attended, by anæmia and disorder of the stomach and bowels. She was speedily cured by measures suitable to these conditions.

We have, in this case, an instance of mental derangement occurring four times in one individual; and in each, chiefly as the consequence of anæmia. The first attack followed copious blood-letting and lowering treatment for nervous symptoms, which, although occasionally, do not invariably depend upon phrenitis. From this cause, she would appear to have been anæmiated at the time of her first confinement; and mania followed as the consequence of the shock of labour in a person so predisposed. In the two last attacks, the existence of anæmia was most marked, and had probably predisposed to them, whilst gastro-intestinal derangement was their immediate exciting cause.

In the following case, the point contended for was better established, inasmuch as the patient had been under my care for some time previously to labour; and the connexion between the anæmia antecedently, and puerperal mania subsequently to it, was clearly shewn.

Case. The patient was a young lady whom I had attended prior to her marriage, and whose illness then was principally dependent upon anæmia and gastro-intestinal derangement. She recovered from this, and shortly afterwards married. This event was soon followed by pregnancy; and, during gestation, the symptoms of anæmia returned in a severe form. Her feeling of prostration at times was excessive. She often fainted on assuming the erect position; became breathless on the least exertion; and palpitation of the heart was readily induced. Her face and lips were extremely pallid; her feet and hands were for the most part cold; and a loud continuous murmur was heard over the jugular veins. So severe were these symptoms towards the end of pregnancy, that it more than once became a question, as to whether premature labour ought not to be induced. By great care, however, by the frequent administration of nourishment to the extent that her digestive powers would permit, and by the use of steel tonics, she was enabled to reach the full period of gestation. Her labour was natural; and she was delivered of a fine boy, without any particular loss of blood, or any unusual circumstance occurring. Everything went on favourably for about five days, when she appeared to be somewhat odd in her manner. From being naturally reserved, she became exceedingly

talkative; her countenance excited; and she represented herself as feeling extraordinarily happy. Her nights had been more or less sleepless; and this sleeplessness now increased. Her mind became more and more disordered; and at length she was perfectly delirious. At the commencement of her attack, morphia was given largely; but it failed to do any good. The tartrate of antimony was then had recourse to; but it proved equally inefficacious. These remedies were therefore discontinued; and it was determined that the treatment should be solely addressed to the patient's general health, and more particularly the improvement of her blood. With this view, she was at once removed from town to a more healthy and open situation. Her apartment was kept freely ventilated; and she was supplied frequently with light unstimulating food. The drain upon her system, occasioned by lactation, was checked by the application of ice and cold evaporating lotions to the mammæ. The utmost tranquillity was maintained; and all sources of excitement, such as interviews with her husband and relatives, were interdicted. Under this treatment, and with the aid of very little medicine, her health soon began to improve, as did also the condition of the blood. As this took place, she slept at night without the aid of narcotics, and her mind became rational. In the course of three weeks she was perfectly convalescent, and has continued well ever since. Two years ago she was again confined, gave birth to a fine healthy child, and recovered without the return of an unfavourable symptom.

I might add other cases of a similar nature, justifying the same conclusion, if the limits of this paper would permit; but I forbear doing so, because it appears to me that sufficient has been said to show that there is a connexion between the existence of anæmia antecedently to labour, and the occurrence of mania subsequently, and that this connexion is more than casual. It has been said that puerperal insanity will occur under very different circumstances; and that stout persons, as well as those who are spare, are equally obnoxious to it. It must be remembered, however, that a stout adipose subject is not necessarily a healthy one; and that in such the blood may be, and constantly is, either impoverished or scanty. The existence of anæmia cannot be determined by the conformation of the patient. It is rather to be sought for in the pallid complexion, the paleness of the inner surface of the lips, and of the palpebral conjunctivæ; in the frequent palpitation of the heart, the breathlessness on exertion, the abnormal murmurs heard over the heart and jugular veins, the feebleness of the pulse, and the general coldness of the feet and hands: with these symptoms, there is often languor and lassitude, and general feebleness of the bodily functions. These are the surest indications of the presence of anæmia; and when they are sufficiently attended to, it will often be found to exist where otherwise it might never have been suspected.

That this condition of the blood should favour the occurrence of puerperal insanity, would appear to be highly probable, from a variety of circumstances. In the first place, it is obvious that for the healthy performance of the functions of the brain, as of other organs, it is necessary that there should be a due supply of healthy arterial blood; and that this supply cannot be greatly diminished in quantity, or de-

terioriated in quality, without producing disorder, or a great susceptibility to it. "That the brain is an organ receiving a very great supply of blood; that its vessels are large and numerous; that an increased determination of blood to it, or, on the contrary, a diminution of the quantity conveyed to it, must have an effect upon the cerebral functions; and that the perfect or imperfect state of the intellectual and nervous powers is intimately dependent upon the condition of the circulation within the head, are facts of which no doubt can be entertained.[1] Hence, amongst the frequent consequences of anæmia, may be mentioned an extremely irritable condition of the brain and nervous system. In some cases, this amounts to actual disorder; in others, to a susceptibility, which only requires some casual circumstance to develope into positive disease. Thus, in puerperal patients, when greatly anæmiated, mania may occur as the result of the mere shock and consequences of labour. But when the blood is less impoverished, additional disturbing causes may be necessary; and those which would produce it in a puerperal patient, are similar to those which would occasion it in the non-puerperal state. Of these, mental agitation, shock, or emotion, loss of blood, and irritations of various organs reflected upon the sensorium, particularly of the stomach, liver, and intestines, are the most potential; and the cerebral disorder induced by these in anæmiated non-puerperal persons, is precisely similar to the mania of the puerperal state.

In the second place, the general symptoms attending puerperal mania, are identical with those which are met with in anæmia. The brain and nervous system, it is true, are in a state of extreme excitement; but the condition of the patient generally is one of weakness and exhaustion. The pulse is small and quick; the extremities cold; and the excitement has been truly characterised as "action without power". Moreover, in all the cases which I have seen, loud continuous murmurs were heard over the cervical veins, as well as those cardiac sounds, which are indicative of an attenuated state of the blood.

In the third place, the progress of the disease does not materially differ from various cerebral affections, which are occasionally met with in anæmiated patients; and whilst in each the tendency under favourable circumstances is to recovery, in either the reverse may happen from very similar causes. Thus, in either, congestion of the brain may occur from feebleness or irregularity of the circulation; and, consequent upon this, effusion may take place, leading to a fatal termination. When, again, the malady is protracted, various organic changes may be induced in the brain and its membranes; and these may give rise to permanent insanity, epilepsy, or paralysis.

Treatment. The treatment generally proper for anæmia will be found, upon the whole, to be most appropriate for puerperal insanity. Special indications will require to be fulfilled by special means; and slight forms of the disease will often yield to the unassisted efforts of nature. But when the attack is severe, and resists the natural efforts, as well as specific treatment, it will generally be found that this obstinacy is connected with an aggravated form of anæmia, and

[1] Mason Good. Study of Medicine. Edited by Samuel Cooper. Note by Editor. Vol. iii, p. 61.

that, in proportion as the condition of the blood is improved, will the cerebral disorder disappear.

If the foregoing observations should prove to be correct, and if it should be established as a fact that anæmiated persons are especially predisposed to puerperal insanity, it will follow that the treatment should not only be curative, but preventive. The practitioner, aware of the cases in which there exists a predisposition to the malady, will be forewarned, and prepared to take precautions against its accession. During pregnancy, he will endeavour to improve the condition of the blood and the tone of the nervous system, by attention to diet and regimen, and such auxiliary treatment as may be indicated in particular cases. During labour he will especially endeavour to diminish the shock upon the nervous system, and to prevent or lessen excessive or immoderate hæmorrhage; whilst, during the puerperal period, he will rigidly guard his patient against the influence of those occasional causes, which are known to determine the attack, such as mental alarm, agitation, or emotion, gastric, hepatic, or intestinal irritation, or any organic irritation which is capable of being reflected upon the brain. In short, the indications are twofold; on the one hand, to adopt such measures during pregnancy as are calculated to improve the blood; on the other, to guard the patient, both during and subsequently to labour, against such influences, mental and physical, as have been known to occasion the attack.

The first indication comprises the treatment of anæmia in all its several forms,—a subject which is far too comprehensive and extensive for discussion in the present paper. Its relations, moreover, to uterine and puerperal diseases generally are so important, that I propose to consider it in a separate communication. It should comprehend attention to external circumstances,—habits and modes of life; to the condition of the digestive organs, as well as that of the nervous system generally; to various remote causes of a depressing character, mental and corporeal; and thus should comprise measures both moral and physical, dietetic and medicinal.

The second indication, so far as prevention is concerned, is to protect the patient, both during and subsequently to labour, against the influence of the exciting causes of the malady. These are, for the most part, well ascertained, and comprehend two classes. The first class comprises those which directly operate upon the mind; the second, such irritative disorders of the body, or of particular organs, as are capable of affecting the brain unfavourably, whether by sympathy or otherwise. All painful states of mind should, if possible, be prevented: distress, anxiety, grief, or any emotion, have, in some instances, immediately given rise to an attack of mania; as also have fright, agitation, sudden shock, or alarm. These also should therefore be rigidly guarded against. Of bodily derangements, it may be said, that any "uncommon irritation spreading to the brain", may be the exciting cause; but certain organs sympathise more directly with it than others, and the disorder of these is especially to be attended to. Such irritative disorders may be enumerated in the following order, as regards their frequency, in the causation of the disease: gastric, hepatic, or intestinal, either singly or combined; uterine, and mammary.

The curative treatment of puerperal insanity, should it unfortunately

have occurred, is one of extreme difficulty;—not less so from the nature of the indications to be fulfilled, than from the reluctance of the patient to acquiesce in the necessary measures of treatment. It should comprise attention to at least the following four points:

First. The removal of any exciting causes which may exist, and of any bodily derangement which may have been instrumental in the causation of the disease.

Secondly. The subduction of cerebral excitement, and the restoration of tranquillity to the nervous system generally.

Thirdly. Guarding against the occurrence of congestion, effusion, or other disease of the brain.

Fourthly. Supporting the constitutional powers, restoring the general health, and improving the condition of the blood.

1. The first indication points to the removal of such exciting causes as may have been concerned in the production of the disease. It has been remarked, that these are referrible to two heads: the one operating directly upon the mind; the other consisting, for the most part, of various kinds of irritation in remote parts of the body. When mere emotion has been the exciting cause, and no physical disturbance can be discovered, it is probable that a full opiate, together with extreme quietude, and the constant application of ice to the head, may at once overcome the cerebral excitement, and avert any further bad consequences. It must, however, be remembered that opium is contraindicated, whenever gastro-intestinal irritation exists as a consequence of the presence of crude, unhealthy, or indigested matters in the stomach or intestines. When, therefore, the tongue is furred, the breath unpleasant, the alvine discharges scanty and unhealthy, as also when the abdomen is tumid and uneasy,—evacuant medicines should precede its administration. If gastric disorder exists in a marked manner, there can be no question as to the advantage and safety of giving an emetic, for the purpose of effecting the direct removal of gastric impurities; and ipecacuanha, with squills with or without the tartrate of antimony, according to the strength or debility of the patient, answers well for this purpose. Full vomiting will generally follow its exhibition; and if solid matters, such as undigested food, be not thrown up, there will often be an evacuation of vitiated, unhealthy secretions, in large quantity, which will be productive of much relief. Having premised this step, the next should be to act upon the liver and bowels, not only for the purpose of carrying off irritating matters, but of promoting secretion from them, as well as elimination. Calomel and jalap combined, are extremely efficacious for the purpose, and should be given in full doses; but when they fail, or are otherwise objectionable, I believe that croton-oil, with the watery extract of aloes, and a little Castile soap, will be found of signal service. I have certainly found this to answer well in these cases. It also should be given in decided doses, and repeated every four or six hours, until the necessary evacuations have been obtained. These will generally consist of a number of fœtid and unhealthy stools; and, when they have been voided, the symptoms will often manifestly improve, whilst the further management of the case will be considerably simplified.

11. The second indication refers to the necessity of allaying the inordinate cerebral excitement, and of restoring tranquillity to the ner-

vous system generally. These objects will be best attained, the former by the exhibition of tartar emetic in small and frequently repeated doses; the latter by opium, morphia, henbane, or some other narcotic. The tartrate of antimony may be given to the extent of one-sixth or one-eighth of a grain every half-hour or hour, until the desired effect is produced; and it is sometimes advantageously combined with small doses of the sulphate of magnesia. Any disposition to vomiting may be obviated by the addition of the hydrocyanic acid; and some have found it useful to add a few drops of the tincture, or sedative solution of opium, to each dose.

The administration of opium, in these cases, requires much caution, and careful consideration of the circumstances. Opium, I would observe, has a twofold action upon the economy; and each is distinct and dissimilar. Upon the functions of animal life it operates as a sedative; upon those of organic life, as a stimulant; and thus, whilst on the one hand, it lowers inordinate action of the brain and spinal cord, it tends, on the other, to exalt the activity of the vascular and organic functions. Hence, its efficacy is greatest in those cases in which the sanguiferous system is most depleted, and the vital and organic functions are most depressed; and, conversely, its employment is least proper where there is a tendency to vascular fulness, whether general or local, and more especially of the encephalon. In proportion then as the pulse is rapid and weak; in proportion as organic debility prevails, and there is an absence of cerebral congestion or determination,—is its use indicated in this disease; and, whatever may be the intensity of the mental excitement, in such cases it may be given fearlessly and freely. When, however, these conditions do not exist unequivocally, as will happen in the majority of instances, it must be had recourse to more guardedly, and its action modified according to the particular circumstances of each. "Opiates have been given with two intentions," says Denman; "some have merely proposed to soothe and moderate the violence of the disturbance by the frequent repetition of small or moderate doses; others have aimed, by the more liberal use of opium, often repeated, to suppress the irritability altogether. As far as I can judge, the former method is far preferable to the latter; and I think there can be no doubt but that opiates in larger doses, instead of diminishing, add, in no small degree, to the irritability which before existed."[1] It is certainly impossible for any one to lay down a rule, applicable to all cases, for the administration of opium, or any other narcotic, in this disease. I have found full doses at bedtime, with smaller during the day, to answer well in some instances; and it is sometimes useful to alternate the use of one narcotic with that of another. Tranquillity and sleep are the great desiderata to be attained; and different medicines, and different modes of exhibiting them, will be required in order to attain this end in different cases. It is, however, most necessary to watch the effect of such remedies, and not to push them beyond certain limits, when their efficacy is questionable, merely in deference to popular custom or opinion.

As auxiliary to these measures, the pediluvium, sinapisms to the

[1] Denman. Introduction etc., Seventh Edition, p. 503.

calves of the legs, and revulsives to the extremities, may often be had recourse to with advantage. The use of the pediluvium was especially recommended by Dr. Robert Whytt; and he gives, in illustration of its utility, the following case, which would appear to have been one of puerperal insanity. "A lady, aged about twenty, on the fourth day after being delivered of her first child, began to be feverish, and slept none. After this she became very delirious, talked constantly, had sometimes tremors, and was so restless, that for two days she had not lain one minute in the same posture, and was with difficulty kept in bed by two or three nurses. On the tenth day after her delivery, when I first saw her, the symptoms now mentioned were all increased, only she spoke none, and seemed to understand nothing that was said to her; her pulse, which was but of moderate strength, beat above one hundred and fifty times in a minute,—nay, once, when she was more agitated than usual, it rose to one hundred and eighty strokes in that time, and became withal very small. As she had been blooded, and blistered, and used several other remedies, *without advantage*, I ordered her feet and legs to be put immediately into the warm *pediluvium*, which was done by making her sit up on the bedside. At first it required two people to keep her feet in the water; but in less than a quarter of an hour she grew calmer, and made little motion, either with her legs or any other part of her body. After using the pediluvium for half an hour, she was put to bed, but soon began to grow as restless as formerly; upon which account warm fomentations were applied to her legs and feet, and renewed, from time to time, for near two hours, but without any benefit. I therefore thought it best to renew the pediluvium, which was used, at this time, for a full hour. It soon made her sit quiet; and, after she was put to bed, although she did not sleep, yet she lay several hours without tossing as usual, and her pulse was reduced to 136. As often as she began to be any ways restless, the pediluvium was renewed. After using it the fourth time, she got several short sleeps, was less delirious, and her pulse only made 120 strokes in a minute. From this time (viz., the eleventh day after her delivery), the pediluvium, which was never repeated above twice in twenty-four hours, procured her longer sleeps, and lessened all her bad symptoms; so that, in two days more, she was quite free of the delirium, and her pulse did not exceed ninety in the minute."[1]

III. The next indication to be attended to, is to guard against the occurrence of congestion, effusion, or other disease of the brain. Such consequences might frequently be anticipated from the extreme cerebral disturbance going on; but, under proper treatment, they are fortunately rare. Nevertheless, the possibility of their occurring must not be lost sight of; and every precaution should be taken to avert them. The state of the circulation in these cases generally forbids the employment of active measures: general blood-letting is, for the most part, inadmissible, and hence abstraction of blood should be limited to the application of a few leeches to the temples, or behind the ears, when circumstances render local depletion necessary; but the constant application of ice to the head, the free use of purgatives, a careful diet,

[1] On the Nature, Causes, and Cure of Nervous Disorders, etc., pp. 453-54-55.

and tartar emetic in contrastimulating doses, is safer practice, and will generally obviate all danger on this score.

IV. The last indication points to the necessity of sustaining the patient, restoring her general health, and improving the condition of the blood. These are matters of the utmost importance; and, upon their due fulfilment will her recovery mainly depend. The means to be employed for these objects comprise all those measures of diet and regimen which appertain to the treatment of anæmia. The patient should be placed in a large, cool, and well-ventilated apartment; her diet should be carefully attended to, and this, in the early stages of the disease, should consist of light, unstimulating food, administered regularly and frequently, but in small quantities at a time. While there is much heat of skin, a quick pulse, and great excitement, milk, gruel, arrow-root, and sago, or other farinaceous articles, form the best diet. As the excitement and febrile disturbance subside, a little animal food, or fish, may be added; and, if the extremities should become cold, and the pulse very feeble, wine must be given in addition, and this sometimes largely. In severe cases, it will be necessary to check the drain upon the system occasioned by lactation; and for this purpose, evaporating lotions should be applied to the mammæ, whilst the bowels are kept open by saline aperients. In conjunction with these measures, the patient must be kept perfectly tranquil. All interviews with friends and relatives had better be prevented; conversation should be prohibited; and a regular nurse, accustomed to the care and management of the insane, should be in constant attendance. It is unnecessary to add, that so long as the patient is under the influence of any mental delusion, she must be strictly watched, and every thing kept out of her reach, with which she might do injury to herself or others.

Under this system of management, the progress of the case will generally be satisfactory; and, as the general health improves, the mental aberration will disappear. Should it be otherwise, additional measures for the restoration of the health will be necessary. Change of air will prove serviceable, and recourse may be had to tonics in addition to the regimen laid down. Of these, it would be advisable to commence with the mildest,—such as the mineral acids, or some light bitter; and, afterwards, to prescribe the more powerful,—such as quinine, or some of the preparations of iron.

I conclude, then, by observing, that the relations which subsist between anæmia and puerperal insanity are often of a very intimate nature; and that too much care cannot be paid to the investigation of this point. I do not contend that *all* forms of puerperal mental disorder are dependent upon anæmia; for I believe that they may arise from other causes, and be connected with other states of the blood:—but I maintain that the asthenic forms of the disease are by far the most frequent, and that of these anæmia constitutes an important pathological element. I believe, moreover, that a careful consideration of this point will often enable us to anticipate and avert the attack, or, when it has occurred, suggest the best method of treatment.

Chester Place, Hyde Park Gardens, May 1851.

ON THE HEALTH OF LONDON DURING THE SIX MONTHS TERMINATING MARCH 29, 1851.

By JOHN WEBSTER, M.D., F.R.S., Fellow of the Royal College of Physicians, Consulting Physician to St. George and St. James's Dispensary, etc.

Since my last half-yearly Report on the Health of London, published in the twenty-fourth number of the London Journal of Medicine for December 1850, 27,954 persons have died in the metropolis during the six months extending from September 30, 1850, to March 29, 1851. Throughout the first quarter, embraced in the following report, the health of London has been, unquestionably, more favourable than during the three parallel months of 1849. The total deaths in October, November, and December of 1850 were 12,544; whereas, throughout the same period of the preceding year, they amounted to 12,877; thus making a diminution of 333 in favour of the latter period. With reference, however, to January, February, and March of the current season, the result has proved quite otherwise; as it appears that 15,410 persons died in London during that period, which number, if compared with the 13,219 deaths reported in the similar quarter of last year, gives an increase of 2,191, or 16·57 per cent. This excess of deaths, it seems important to mention, was chiefly confined to the last four weeks of the above period; when the total number of fatal cases recorded amounted to 5,478; whereas, during the parallel period ending March 30, 1850, they only reached to 4,035; thus making an augmentation of 1,443 deaths in the similar four weeks of the current year.

Pursuing the plan adopted in my former reports, I now proceed to offer some general remarks on the principal diseases which exhibited either a diminution, an increase, or an uniform rate of mortality, during the six months comprised in the present communication. From the facts brought forward to illustrate the sanatory condition of our enormous metropolitan population, readers may form their own opinions, altogether irrespective of my conclusions from the same premises.

Diseases which have lately exhibited a Diminished Rate of Mortality. During the last six months, the disease which manifested the most marked diminution in its rate of mortality was cholera, only thirty fatal cases having been recorded, instead of 502 reported during the parallel two quarters of 1849-1850. It is also interesting to mention, that not more than seven examples of this disease were met with in the whole of London during the three first months of the current year.

Diarrhœa and dysentery, like cholera, have also prevailed less violently in London during the past six months, than in the same months of 1849 and 1850. From the first complaint, 539 deaths occurred instead of 689 in the former period; whilst there were only 71 fatal cases of dysentery, in contradistinction to 122, similarly compared.

Measles and scarlatina, likewise, have each exhibited a diminished

rate of mortality. Of the former complaint, only 627 fatal cases have occurred, in lieu of 641 during the parallel period of 1849-50. In scarlatina, although the difference is also inconsiderable, there has still been a diminution; 635 deaths being reported, instead of 685, which occurred during the six months ending March 1850.

Apoplexy and paralysis come also within this category, both maladies having recently proved less fatal than in the former parallel season. From the first named complaint, 646 persons died during the recent six months, instead of 700 reported in the season 1849-50; whilst 560 deaths occurred from paralysis, in place of 623 during the corresponding quarters of the previous year.

Although the total number of persons who lost their lives by violence in London has been greater than in the previously quoted period, some of the casualties are less considerable. For instance, during the six months terminating the 30th March 1850, 727 persons died by violent deaths; whereas, during the six months comprised in the present report, the total number amounted to 833, being an increase of 106, or nearly one-seventh. Of the particular kinds of violence followed by death, fractures constituted the most frequent; then burns and scalds; whilst drowning was also common, of course amongst the river population. In deaths from burns and scalds, however, there has recently been some diminution, 149 individuals having lost their lives in this way, instead of 164 reported during the parallel six months of the previous year. It is also deserving of notice, that during the last quarter, 115, a very large proportion of these fatal cases, occurred in young persons under fifteen years of age. This fact probably indicates, that such accidents chiefly occur in private houses and domestic circles, and not in manufactories or public establishments, where adults are principally employed. At all events, children and young people have been the most frequent victims of burns and scalds.

Diseases which have exhibited an Increased Rate of Mortality. Notwithstanding that the health of London has been satisfactory during the last half year (except in the month of March), several diseases have proved more prevalent than usual. To these I would now briefly direct attention, as being indicative of the unhealthy character of part of the more recent season. Diseases of the organs of respiration have generally become much more fatal during the six months just terminated, than throughout the parallel quarters of the previous year. In the last-named period, the total deaths from diseases belonging to this division, were 4,935; whereas, during the six months ending the 29th of March 1851, they amounted to 5,784,—making an increase of 849 fatal cases, or 17·20 per cent.

On examining the subject more in detail, it appears that bronchitis exhibited greater fatality this year than in the previous; 2,534 deaths having recently occurred from that complaint, instead of 2,089, which were met with during the preceding parallel two quarters. From pneumonia, the deaths during the more recent season amounted to 2,190, instead of 2,000; and, by asthma, 599 persons died, in lieu of 474 reported during the previous period: whilst influenza, which proved fatal to 87 persons in the two quarters ending the 29th of

March 1850, caused death this year in 231 instances,—the largest proportion of such cases having occurred in the month of last March, when that complaint prevailed almost epidemically.

Small-pox has likewise been recently more prevalent than formerly, 466 persons having died of that malady during the last six months, in contradistinction to 194 fatal cases, of the same description, which occurred in the parallel quarters of the previous year. Indeed, variola has prevailed throughout the metropolis more extensively during the last three months, than at any period in the preceding two years. This is shown by the fact, that only 518 persons died from small-pox, in London, during 1849, and not more than 498 in 1850; so that nearly as many individuals have already fallen victims to it, from the 1st of January to the 29th of March in the current year, as throughout the whole of either of the preceding twelve months. This feature of the present season deserves special attention, and ought to render the public more anxious to second the efforts made by the profession and the legislature to disseminate genuine vaccination, which is truly the best and safest preventive of variola.

Hydrocephalus, hepatitis, rheumatism, convulsions, and typhus fever, have also proved more fatal during the period referred to in the present report, than in the previous year. From hydrocephalus 716 deaths have occurred, instead of 684, during the former six months: from hepatitis 99 fatal cases, in contrast to 73; from rheumatism 121 instances, instead of 116 previously reported; while convulsions caused death in 1013 individuals, in place of 955 during the former period; and lastly, from typhus fever—at all times a good indication of public health—instead of 962 fatal cases formerly reported, 1140 occurred, of which 171 took place during the month of March in the current year; whereas only 126 deaths by the same cause were recorded in the same month of 1850. This shews that in this disease, as well as in some other maladies, the recent spring has proved more unhealthy than the preceding.

In addition to the diseases now enumerated to have prevailed less fatally than previously, erysipelas also deserves notice. The fatal cases amounted only to 168 during the last six months: whereas 228 cases were met with in the parallel two quarters of 1849-50. Like general dropsy, ascites has been also less frequent than previously, although not to any considerable extent,—58 deaths from this malady having been reported throughout the period embraced in the present report, instead of 63 cases during the former half year. Other illustrations of a similar character might be quoted.

More persons lost their lives by fractures and contusions throughout the metropolis, during the last six months, than in the parallel period ending March 1850; the number of accidents having amounted recently to 305, in contradistinction to 268 reported in the former two quarters. Deaths by drowning have been, unfortunately, also of late more numerous; 129 persons having perished in this manner, instead of 95 during the period previously quoted. The number of persons who lost their lives by hanging and suffocation, during the past six months, was likewise considerably greater than in the same period of the previous year; 125 deaths, by these causes, are now

recorded, in contrast with 86 cases of a similar description in the two quarters terminating the 30th of March 1850. In deaths from wounds the difference was, however, in favour of the former season; 47 persons have died from the above cause during that period, whereas 54 fatal cases were recorded in the six months ending the 29th of last March. The total augmentation of deaths reported from the casualties now mentioned, and other violence, occurred during the last quarter, viz. in January, February, and March of the current year, when not less than 476 persons lost their lives by fractures, drowning, hanging, suffocation, and wounds, etc., in contradistinction to 386 violent deaths of the same severe description, during the parallel three months of the preceding year. Such facts indicate the dangerous occupations of various persons in this great metropolis; whereby numbers are cut off annually, and even to a greater extent than the public generally would perhaps believe, unless upon the most irrefragible evidence. Medical men are fully cognizant of the large numbers of their fellow-creatures who every year die violent deaths, especially among those who form the actual population of London. Those, however, who live in affluence, or pass their days in amusement, and never visit the workshops and crowded haunts of industrious men, know very little indeed respecting the dangerous nature of many occupations therein; whereby health is frequently impaired, and life often endangered. These facts deserve attentive consideration, with a view to prevention of similar accidents in future.

Diseases exhibiting nearly an uniform rate of Mortality. Diseases affecting the kidneys and urinary system, have genarally manifested a remarkable uniformity in the number of deaths; 309 individuals having died from these causes during the last six months, instead of 307 in the previous parallel period. From dropsy, 414 persons are reported to have died, in place of 419. From hæmorrhage, 103, in contrast to 106 previously reported. From phthisis 3,247 individuals perished in the metropolis during the last two quarters, instead of 3,099 in the former period, already so often quoted. From cancer the number of deaths was identical, 455 having been recorded in each of the six months alluded to. From enteritis 178 deaths were reported, instead of 170 last year; and from peritonitis the fatal cases recently amounted to 102, in place of 104 met with during the parallel six months ending in March 1850. Several other maladies manifested considerable uniformity in their rates of mortality. Sufficient data have thus been stated, in the present and previous reports, to prove that, unless under particular circumstances, the ratio of deaths from certain diseases, even amongst an enormous metropolitan population, ranges often within nearly the same uniform standard; but which may be of course, at times, influenced by season, and various collateral external circumstances.

Age of Individuals who have recently died in the Metropolis. A very large proportion of the deaths recently recorded, were amongst young subjects. Indeed, in reference to this very important characteristic of diseases affecting the population of London, I would repeat, in the words of my last report, when alluding to this

subject, that "the large number of children who annually fall victims to disease in London, exhibits a feature in the mortuary reports of the metropolis, which ought to arrest the deepest attention." Great as the proportion then was of individuals cut off before they had arrived at the age of puberty, the number of deaths similarly classed has scarcely diminished; 12,345 persons under fifteen years of age having died during the last six months, which is 44·19 per cent. of the entire mortality within that period. Those dying from 15 to 60 years of age, amounted, on the other hand, to 9,227, being 33 per cent.; whilst 6,252 individuals, or 22·36 per cent. of the whole number, were upwards of 60 years old; thereby leaving 130 persons whose exact age was not registered. The above facts, nevertheless, demonstrate satisfactorily that, notwithstanding many individuals may die prematurely in England, still a large number of the inhabitants attain considerable longevity, if not greater than in any other country of Europe, or even throughout the universe.

Having already adverted to various diseases, which frequently prove very destructive to life amongst children and young persons, it seems unnecessary again to resume that part of the subject. However, one important cause of death amongst infants, merits more than a passing remark at present; as the evil already alluded to in former reports, unfortunately appears increasing. I allude to the "privation of breast-milk", the best nourishment for infants during the first months of their existence. From the want of this, 107 infants perished in London during the last six months; and if the 89 individuals similarly sacrificed in the two quarters immediately preceding be added, it appears that 196 helpless fellow-creatures have fallen victims to this privation during the period of twelve months. This was doubtless, in some instances, the consequence of fashionable mothers neglecting to suckle their own offspring, or, in others, to the poverty of parents, tempted to leave home and their new-born children by the inducement of high wages, ample food, and many creature-comforts they would enjoy as wet-nurses in the houses of the more opulent. Such a custom, unless in particular instances, when the mother is totally unable, from disease or physical causes, to nourish her own infant, should be discountenanced; since experience amply proves, that any deviation from the law of nature, is generally detrimental both to parent and child.

Mortality among the Pauper Population. Similar to the result stated in my last report, the proportion of fatal cases met with, in all the charitable institutions of London, is considerable. Amongst the 27,954 deaths registered during the six months terminating on the 29th of March 1851, almost one-sixth, or 4,451 persons, died in the workhouses, asylums, prisons, and hospitals; which indicates that near 16 per cent. of the total mortality occurred in the above class of the population; many of whom were treated gratuitously during their last illness, besides being supported at the public expense. This fact is creditable to the richer classes of society, and shews the extensive practical benevolence thereby disseminated among the less fortunate part of the community: particularly in the liberal support of numerous public charitable institutions, in which the 4,451 deaths, now alluded

to, were recorded. The majority were male inmates; 2,487 of that sex having died in the above establishments, the remaining 1,964 being females; hence giving an excess of 523 in the former class, or 26·62 per cent. more deaths amongst male than female residents.

Besides the above, a considerable proportion of the deaths, recently recorded, were patients treated at dispensaries. At the dispensary with which I am connected, amongst the 3,161 patients treated by the medical officers of the charity, during the last six months, 58 deaths were reported; being at the rate of one fatal case in every fifty-four and a half admissions. Therefore, if the casualties at every other similar metropolitan institution are taken into account, it must consequently be acknowledged, that the mortality amongst the labouring classes is always very considerable.

Workhouses. Upwards of half the entire mortality amongst the pauper population of London, during the last six months, took place in these institutions. The majority were female inmates; the exact numbers being 1,237 men, and 1,347 women, making a total of 2,564 deaths, or 9·17 per cent. of the whole number. Another feature also deserves notice; viz., that 786 of the above deaths, or nearly one-third, were reported during the last six weeks of the period embraced in this report; which will assist to explain the augmented mortality already stated to have prevailed during the recent season. Many of the fatal cases occurred in persons of advanced life, although a number also were young children; in fact, disease generally has recently proved more destructive to these two classes of individuals, than to persons at the prime of life. Of the deaths recorded in workhouses, only one-fifth, or 543 out of 2,564, of the whole number, occurred in those situated south of the Thames. This is more important, as the total number of inhabitants of the southern districts only amounts to about one-third of those resident on the northern bank of the river. Hence it may be confidently inferred, that sickness has lately prevailed less extensively amongst the pauper population of parishes in the Surrey division, than on the Middlesex side of the Thames, notwithstanding the lower situation, and the admitted greater frequency of epidemic diseases in the former district. Its liability to epidemic influence was remarkably illustrated in former times, during the prevalence of plague; and more recently in 1849, when upwards of half the deaths from cholera took place in the southern division of the metropolis, although it had a much smaller number of inhabitants.

Lunatic Asylums. The total number of deaths in establishments for insane patients, during the past six months, amounted to 221; of whom 116 were male, and 105 female lunatics. This appears a large mortality, especially if contrasted with the previous summer and autumn quarters, when the aggregate deaths, in the same institutions, were 171. The results now mentioned are, however, consistent with general experience; since death oftener supervenes, amongst lunatic patients, during the cold and severe weather of winter, than in temperate seasons; notwithstanding that mental disease more frequently attacks individuals in the hot days of summer, than in the colder months.

The above comparative amount of fatal cases, met with in the two sexes of lunatics, is also interesting; as the figures now quoted fully bear out a remark which I have made elsewhere; namely, that "mania, although more common among women, is in them more curable, and less fatal than among men". A larger number of female lunatics being usually under treatment in the metropolitan asylums than of males, the occurrence of 105 deaths among the former sex, in contrast to 116 among the latter, strongly supports this view; especially if the facts recorded in my last report be remembered, wherein it is stated, that 96 insane male patients, and only 75 females, died during the period therein included. According to the above data, besides others which might be quoted if necessary, a more unfavourable prognosis of the termination, in cases of insanity, may be given, *cæteris paribus*, in men than women; whilst a greater number of recoveries may be confidently expected in the latter, than in the former class of lunatics.

Metropolitan Prisons. I now approach a most important subject of inquiry, as well to members of the medical profession, as to legislators and philanthropists. Into the whole of this interesting question, the present is not, however, the proper place to enter at any length; the point, now under discussion, being simply the mortality recently met with in these public establishments. Judging from the number of deaths reported in all the prisons of London, during the last six months, the inmates seem to have been healthy, and the localities salubrious, with the exception of Millbank. Notwithstanding that the average number of prisoners in the metropolitan gaols, including the hulks at Woolwich, usually amounts to about 6,120, and that even these are often changed, only 27 inmates have died during the last two quarters; 20 being men, and 7 women. This constitutes a very small rate of mortality; and as eleven of the above cases, or 10 men and 1 woman, were reported from the Millbank Penitentiary, it hence becomes evident, that residence in a London prison, speaking generally, seldom proves inimical to the bodily health. Millbank, however, does not appear so salubrious as several of the other prisons; for two-fifths of the entire deaths in these institutions, now reported, took place there; although the number of prisoners only averages about one-fifth the total amount. When we reflect on the statements promulgated, in ancient times, respecting the insalubrity of the London gaols, it is highly satisfactory to find, whatever difference of opinion may still prevail in regard to the discipline in force in certain quarters, that, with the exception just mentioned, the physical health of the majority of prison inmates is often better within, than without the walls of these receptacles. This is, doubtless, in great part, owing to the sufficient and wholesome dietary allowed to prisoners, as well as to their being less exposed to the demoralizing influence of vice and intemperance. It is farther worthy of note, that at the City Bridewell, although situated in a densely populated neighbourhood, and having Fleet Ditch on one side, with Puddle Dock very near the other, only one prisoner died during the last two years; namely, a female from phthisis of long continuance; notwithstanding the number of com-

mittals amounted to 2,108 during the above period. The principal complaints noticed among the inmates, have been cutaneous and venereal disorders: whilst the number of infirmary cases have seldom exceeded three at one time. It is also important to state, when the cholera prevailed with great intensity in this district of London, during the autumn of 1849, not a single case occurred within the walls of Bridewell. This exemption becomes more remarkable, when it is considered that a large proportion of the prisoners here confined, were, it may be said, predisposed to such a disease, from the destitute condition to which many of the vagrants were reduced previous to their committal.

Lying-In-Hospitals.—The mortality reported from these public establishments, of which there are four within the metropolis, has been very moderate; indeed, the rate was much under that recorded during the previous six months. The number of deaths met with, throughout the two quarters, embraced in the present report, was only fourteen, of whom seven were children, and the rest women. It should be also remembered, that eighteen deaths during child-birth occurred in the same institutions, during the two quarters immediately preceding, besides the deaths of twelve children. These statements and facts indicate, that the condition of lying-in institutions has been recently more salubrious than ordinary; whilst no puerperal epidemic malady seems to have prevailed in any of these hospitals, which sometimes presented, in former years, a very high rate of mortality.

Hospitals for Special Diseases. Within this category, four hospitals are now comprehended, upon each of which establishments I propose making a few general observations. In order, however, to secure accuracy respecting the number of patients admitted, and the total amount of cures and deaths recorded, I addressed a note to different friends officially connected with the several charities, to which applications they all courteously replied, giving me the figures contained in the subsequent statements. To these gentlemen I would now return my sincere thanks. Not only is the information valuable, which has been thus furnished, to myself individually, but the various facts and data will likewise prove highly useful to other observers. The first special institution which merits notice, is that appropriated to syphilitic diseases.

Lock Hospital. During the last six months, 166 patients have been admitted into this establishment, consisting of 85 men, and 81 women, whilst 128 persons were discharged cured, comprising 71 male and 57 female patients; but no death occurred throughout the entire half year. It hence appears, the ratio of cures, in both sexes, was 77 per cent,—the mortality *nil*. In regard to male patients, considered separately, the proportion of cures was greater than among females; 83·53 per cent. of the former, and only 70·37 per cent. of the latter sex has thus been discharged convalescent. It may therefore be inferred, that most complaints affecting female inmates of the Lock hospital are of a more inveterate character, and require a longer

period for their treatment, than diseases usually affecting male patients, although the numbers of both sexes admitted were nearly identical. This inference may perhaps appear as not yet sufficiently proved by the facts adduced; nevertheless, the deduction is reasonable, and I now venture to express such an opinion, believing it deserves mature consideration, and will be verified by more extensive experience.

Hospital for Consumption, and Diseases of the Chest (at Brompton). Phthisis unquestionably constitutes the most fatal disease affecting the inhabitants of this country. The average annual mortality from that complaint usually amounts to about 7,000 deaths, in London alone; whilst, throughout England and Wales, the number ranges near 55,000 per annum. Such mortuary details sufficiently indicate the prevalence and severity of this malady, amongst all ranks of the population. With a view to investigate, and to treat specially pectoral complaints, the charity adverted to in the present paragraph was some years ago established; and into it, according to an official return kindly furnished on my application, 194 patients, consisting of 118 men, and 76 women, were received during the six months embraced in this report. The number discharged "more or less relieved", as stated in the document already mentioned, was 88 males, and 70 females; thus making a total of 158 individuals. Whether any patients were ultimately cured, it is difficult to say definitively, as the statement supplied does not contain particulars relative to that circumstance; indeed, I have been informed, the word "cured" is never entered upon the registers of this institution, as it might give rise to erroneous impressions, or lead to discussions which could produce no beneficial consequences. The deaths reported during the six months embraced in the present report, amounted altogether to 33, of whom 22 were men, and 11 women; hence, the gross mortality recorded at the Consumption Hospital, compared with the number of admissions, reached 17 per 100. However, on separately comparing the mortality amongst the two sexes, it appears, the ratio actually amounted to 18·64 per cent. in male, and only to 14·47 in female patients, which shews, that consumption proved, at least during last winter, comparatively less fatal to the latter, than the former class of inmates; although, it is well known, that the disease more commonly attacks women than men in this climate. In proof of such an opinion, besides the fact, that during the two quarters immediately preceding, the proportion of deaths in the two sexes, at this charity, was somewhat different from the present, notwithstanding 33 fatal cases were also then reported, of whom 15 were female and 18 male patients, I would mention, that in 1847, 25,083 males died of phthisis, against 28,234 females similarly affected, throughout England and Wales. This statement also shews, that nearly as many persons are annually carried off by consumption, as by typhus and pneumonia combined, which form two of the next most deadly complaints prevalent at the present time in Great Britain; seeing that 30,320 patients lost their lives from typhus fever in the year just quoted, and 23,447 from inflammation of the lungs; thus making an aggregate of 53,767 indivi-

duals who became victims to the above-named maladies. Another feature indicating the great prevalence of pectoral disorders in this country, and also their severity, may be referred to as evidence,—namely, that almost one-fourth of the total deaths recorded by the registrar-general, including consumption, usually arise from affections of the respiratory organs. This occurred during 1847, when, in a total mortality of 420,977, not less than 104,432 fatal cases were reported from diseases of the lungs, and of the other organs of respiration; to which statement, it may be also added as an important fact, that one person in every 310 of the whole population annually dies of consumption.

Small-Pox Hospital. During the six months terminating on the 29th of last March, 264 patients affected with variola were admitted into this institution, whilst the deaths amounted to 46; consequently, the mortality averaged 17·42 per cent., or nearly two in every eleven cases. Considering the malignity which variola so often exhibits, the above ratio of deaths does not appear excessive; but, if the fact be also taken into account, that about two-thirds of the patients admitted had been previously vaccinated, the results now reported assume quite another aspect, as they then shew, that either the individuals had never been properly imbued with cow pox, or if vaccinated, its protective influence had become worn out, or eliminated from the system. Respecting vaccination, as a protection against small-pox, this is not the proper place to investigate cursorily so important a question; nevertheless, I would express my conviction, that in a very large majority of persons, who exhibit the genuine cow-pox, the likelihood of being attacked by variola is very small; but if this should happen, the prospect of a fatal termination is more improbable.[1]

In addition to the 264 patients attacked by genuine variola, and removed into the small-pox hospital, six individuals affected with eruptive diseases, not variolous, were likewise admitted. Amongst these, however, no death occurred; consequently, altogether, 270 persons were treated as inmates, about one-third only being females; hence, the disease seems to have been, according to the above data, twice as common in men as in women. This conclusion coincides, in some degree, with general experience; and it may be stated, in proof of its correctness, that in 1847, when 4,227 deaths were recorded from small-pox, throughout England and Wales, 2,230 took place in males, and only 1,997 in females; thus giving 233 more fatal cases amongst the former than the latter sex, although women are considered to be the most numerous class in this country.

In comparison with the number of deaths now recorded as caused by small-pox, it may be interesting to mention, that nearly one hundred years prior to the time already quoted, viz., in 1749, notwithstanding that the population of London was only about 780,000, or scarcely one-third its present amount, no less than 2,625 persons died from variola in the metropolis, one-tenth of the total mortality being

[1] The reader is referred to the able exposition of this subject by Dr. A. Knox, in the London Journal of Medicine for December 1850, and April 1851.

then alone occasioned by this malady. Even subsequently to the introduction of inoculation, authors state that, one in every fourteen inhabitants born in England became the victims of small-pox—so malignant was this complaint at the above period. Now, however, and even in spite of the prejudices frequently still entertained by parents, especially amongst the lower ranks, who are often very adverse to employing vaccination, this scourge of the human race has, nevertheless, proved much more rare in many districts of England. Such an opinion seems more correct, when it is known that, only one person in about every 85 individuals born at present dies from small-pox; whereby, this disease, from being formerly the most fatal malady amongst the population, has fallen to a much lower position in the mortuary scale, and now occupies usually the fifteenth place on the list of deaths.

Fever Hospital. In this establishment, now situated at Islington, the deaths recorded amongst the inmates, during the last six months, amounted to 42; of which 19 occurred among the female, and 23 among the male patients. Compared with the mortality met with throughout the two quarters immediately preceding, the amount just mentioned is rather less than that previously reported; seeing that 50 patients then died in the Fever Hospital, of whom 26 were male, and 24 female inmates; whereby the proportion of the former sex was predominant at both periods.

Believing that it may prove interesting to make a few general remarks respecting the prevalence of febrile diseases in the metropolis, during the past year, especially if illustrated by the records of this useful institution, I would observe, that 544 patients were admitted, during the above period, in lieu of 653 the preceding year; thus making a diminution of 109. The numbers discharged cured amounted to 421, or at the rate of 77·38 per cent.; and, as the deaths were 90, the aggregate mortality of all cases, therefore, reached 16·50 per hundred,—being very nearly the average of the two preceding years.

Of the patients admitted during 1850, 357 were affected with continued fever, 59 with scarlatina, and 128 laboured under other diseases than fever. Again, in regard to the numbers dismissed cured, it appears, by the annual report, that 275 persons attacked by continued fever, left the hospital convalescent, 52 recovered from scarlatina, and 94 previously suffering from other diseases, not fever, were restored to health. Amongst the 90 deaths already referred to, 52 occurred from continued fever (including typhus, and the interic, or abdominal variety), making 14 per cent. The rate of mortality in the cases of typhus amounted, however, to 22·4 per cent; and of enteric fever, it was about 18 per cent. Seven patients died of scarlatina, and 31 of other diseases than fever; in which latter category, if calculated according to the admissions, the mortality is 24·20 per cent, being rather a high average. It should, however, be stated, in explanation of the above circumstance, and to mark the severe type of the diseases often affecting residents, that considerably more than half the 90 fatal cases now recorded, or 50 patients, died within seven days after their admission.

Before taking leave of the Fever Hospital and its operations, I must transcribe, from an authorized statement lately published, the follow-

ing paragraph, as it possesses much practical value, besides indicating the prevailing diathesis of diseases recently admitted. During the whole of last year, the report says, "Blood-letting has not been resorted to in a single instance; and, in few cases, was even the topical abstraction called for. On the other hand, it was found, when the stage of depression came on, that wine and other stimulants were, as in several preceding years, the chief measures on which dependence could be placed." In addition to the above important remarks, it is also instructive to add, on the same authority, that ague (ordinarily of comparative rarity in or around London) was last year met with in nine cases received into the hospital; all of whom were speedily cured. This fact becomes more interesting, as sometimes not a single case of periodic fever was admitted for years consecutively.

General Hospitals. In my last half-yearly report on the Health of London, I made some cursory remarks respecting the mortality met with at these establishments, which attracted considerable attention at the time, and led to much subsequent discussion. I again resume the subject more willingly, in consequence of being able, through the kindness of others, to bring before the profession some interesting statistical data, illustrating the movement of patients in various metropolitan hospitals. In order that various facts might be classified in an uniform manner, so that general principles might be established upon authentic evidence, and that, at the same time, the results so obtained from particular institutions might be compared, I forwarded to different friends attached to the eleven general hospitals of London, an exactly similar form, to be filled up, in separate columns, with the number of patients admitted, the number of cures, and likewise the deaths recorded during the six months referred to in the present communication. To the gentlemen thus addressed my best thanks are justly due, for their promptitude in replying to these inquiries; and although I have been unable to obtain an answer to every question, in consequence of the want of a secretary in one case, the labour of examining numerous registers in other instances, as also the fact, that sometimes the hospital books were only made up annually; nevertheless the data supplied were valuable; whilst the various figures given in subsequent tables cannot but prove of much use to practitioners, by enabling investigators to form their own opinions, besides otherwise deducing important practical conclusions. With these objects, the general hospitals of London were selected, since a large number of the sick and labouring poor are therein treated, particularly when suffering from the effects of severe disease, or accidents. The nature of the particular maladies affecting some patients, the kind of violence which had befallen others, or the special cause of death in those cases terminating fatally, however instructive such information would undoubtedly prove to the profession, are not detailed in the present report. Indeed, to make similar attempts, even if they did not terminate in failure, would render this communication not only too voluminous, but almost incompatible with the purpose originally proposed; more especially, as any undertaking of that description could be only accomplished by gentlemen officially connected with the institutions. However, I very confidently trust,

the time is not distant, when periodical reports will be regularly published, containing ample statistical details from all the metropolitan hospitals, so that the desideratum, to which reference is now made, will be effectually supplied; more especially, as the proceeding would be highly advantageous, and also conduce much to the advancement of medical science, based upon the best of all foundations—extensive experience.

Statistics of Patients in Nine General Hospitals of London, during Six Months, terminating at the end of March 1851.

Hospital.	Class of Patients.	Admitted.		Died.		Per Cent.
St. Bartholomew's	Medical ..	891		121		13·58
	Surgical ..	1,796		90		5·01
			2,687		211	7·10

King's College ..	Both classes		659	59		8·96
	Grand Totals		11,838		850	7·18

According to the data contained in this table, the number of patients affected by surgical diseases generally, but especially at the London and St. Bartholomew's Hospitals, predominated over the medical, excepting at the Westminster Hospital. In the first-named charity, the proportion was five surgical to two medical cases admitted; whilst at St. Bartholomew's, the former were exactly double the latter. Respecting the proportion of deaths recorded, the ratio ranged otherwise; being relatively more numerous amongst medical patients at all the hospitals, than in persons treated by the surgeons; and although that number was identical in both categories at the London Hospital, the comparative result was very different. Speaking generally, in reference to the ordinary rate of mortality met with in medical diseases, the mean averaged highest at Charing Cross and St. Bartholomew's Hos-

pitals, as the proportion, calculated upon the numbers admitted, reached 14·52 per cent. in the former establishment, and 13·58 in the latter; the lowest recorded being at the Free Hospital. Again, amongst surgical patients, the smallest mortality occurred at the Westminster Hospital, where the ratio averaged under $3\frac{1}{2}$ per cent.; whereas, at St. Bartholomew's, five deaths occurred for every hundred admissions; but at St. George's Hospital the per centage of deaths among surgical patients was 5·73. Considerable discrepancy is therefore observed to exist in the gross mortality met with at different institutions. Thus, at King's College Hospital, the ratio seems higher than in any other charity, being near nine per cent., both classes included. On the other hand, the Free Hospital exhibits the lowest, or only 4·77 per cent.; whilst at St. George's, the proportion of deaths was 8·60 per cent.; whereas, at St. Thomas's, it was nearly two per cent. less, being almost identical in amount with that recorded at the London Hospital, where a larger number of severe accidents are usually admitted, than into any hospital throughout the metropolis. Other important inferences may be likewise deduced from the various figures given in the table, especially, as they not only illustrate the general mortality met with in various public charities, but likewise state the gross number of patients treated, during the period comprised in this communication.

No answer having been returned to my application respecting the movement of patients at University College, or Guy's, Hospitals, during the last six months, I regret it has been out of my power to enter either of these institutions in the table I have compiled. However, on examining the Registrar General's weekly reports, it appears 70 patients died in University College Hospital during the two quarters ending last March, instead of 78 in the previous; whilst at Guy's, the total deaths were 191 in the recent period, contra-distinguished to 164 in the former; thus making an increase of 27 fatal cases, or about one-seventh. Although it was impossible to procure the requisite return regarding Guy's Hospital, a friend, who obligingly examined the registers, states, that the medical and surgical cases admitted at this charity, from March 1850 to March 1851, amounted to 4,165; the deaths being 349 during the same twelve months; so that, the rate of mortality ranged within a fraction of 9·5 per cent., being higher than that recorded as occurring in any establishment quoted in preceding pages.

Notwithstanding discrepancies may appear in the mortuary details received from several hospitals, during the last six months, as compared with the two quarters from March to October 1850, the total deaths in the more recent period was greater, being 1,111, or 60 above the number recorded in the previous, when the aggregate amounted to 1,051. Even if the first three months of 1851 are alone taken into account, still an increase in the mortality will be found to have supervened in the hospitals, as 604 deaths, or more than half of the whole amount, took place in the months of January, February, and March, in contradistinction to 507 reported during the quarter immediately preceding. It may be farther stated, in proof of the augmented sickness more recently prevalent in London, as compared with the parallel quarter ending in March 1850, that 583 deaths occurred, during that last-named period, in the eleven general hospitals. This result also

confirms the statement given in a former paragraph, when alluding to the augmented mortality lately noticed amongst workhouse inmates.

Thinking some inquiry regarding the sex of patients treated in metropolitan hospitals, would prove interesting, the following table has been constructed with the express object of illustrating that question.

Sex of In-patients Admitted and Died in Six General Hospitals of London during Six Months, terminating at the end of March 1851.

Hospitals.	Class of Patients.	Admitted.		Died.	
		M.	F.	M.	F.
St. Thomas's	Medical.....	405	508	45	47
	Surgical	784	440	31	19
London	Medical.....	321	207	38	25
	Surgical	941	421	43	20
St. George's	Medical.....	347	344	41	41
	Surgical	521	264	32	13
Middlesex	Medical.....	286	341	27	24
	Surgical	413	277	19	7
Charing Cross	Medical.....	91	88	12	14
	Surgical	281	162	10	6
Royal Free	Medical.....	65	30	6	1
	Surgical	117	102	6	2
	Totals	4,572*	3,184	310†	219‡

* Being 1,388 more males than females, or an excess of 43·59 per cent.
† Or 6·78 per cent. ‡ Or 6·90 per cent.

Viewed in a general aspect, the above statement shows that a large proportion of hospital inmates were male patients,—proportions in a hundred being about 59·33 males to 40·67 females. At two institutions, however, the reverse was the case in respect to medical patients, namely, at St. Thomas's and the Middlesex Hospitals. In the former, one-fourth more females than males, labouring under medical diseases, were admitted; and a similar peculiarity occurred in the latter charity, although the difference was less considerable. In the other institutions, more male surgical patients were received into the wards appropriated to that class, than of the opposite sex; particularly at the London and St. George's Hospitals, in both of which receptacles, the number of male surgical patients was about double that of females.

The average rate of mortality in the two sexes, speaking generally, was almost similar; the difference being, however, rather against females, in whom it was nearly 7 per cent.; whereas, amongst male patients, the mean ranged about six and three quarters. This result was occasionally reversed; for instance, at the Middlesex Hospital, the mortality exceeded six and a half per cent. in male patients, whilst, amongst females, it was under five and a half; thus making a difference of one per cent. in favour of the former. On the other hand, at St. George's Hospital, the ratio was identical amongst the medical patients; since, exactly the same number of male and female inmates, of that division, died, whilst the admissions were very nearly equal.

Nevertheless, in the surgical department, the mortality ranged differently, being under five per cent. amongst female patients, and amounting to 6·14 per cent. in the opposite sex. Reasoning from these, and previously recorded premises, practitioners may fairly assume, that the prospect of a fatal termination in male or female patients, when labouring under medical diseases of an ordinary kind, will be nearly alike; whereas, surgical complaints will probably prove more dangerous in the former, than in the latter sex. At the Charing Cross Hospital, deductions somewhat different may be derived from the figures supplied; thus, the proportion of deaths amongst female inmates, of the medical wards, was greater than in males of the same category; the former being nearly 16 per cent., and the latter ranging about 14·28. Nevertheless, amongst surgical patients, the ratio coincided with that of other hospitals; the mortality being 3·55 in male patients attacked by surgical maladies, and 3·70 per cent. in females also of that category. The above conclusions being, however, based upon a limited number of data, they should be, therefore, received as only approximations to the truth; or rather, as a general illustration of the practical knowledge which would be certainly obtained, if a more extensive series of facts and figures were brought into calculation. Indeed, could accurately detailed registers of the public hospitals—kept upon an uniform system—be made available, the benefits, which must thereby accrue to the profession, would prove invaluable; since the medical attendant, instead of feeling otherwise occasionally doubtful, respecting the result likely to supervene in particular diseases, might then foretell future events almost as certainly as actuaries and physicians (conversant with the science of life insurance) now prognosticate the probable age which particular individuals, under ordinary circumstances, may expect to attain.

One of the questions put by me to the officers of general hospitals, referred to the proportion of patients discharged cured. Owing, however, to the difficulty of separating absolute cures from cases which left the wards relieved, with a fair prospect of future convalescence, it has become impossible to discuss this point in a satisfactory manner. Notwithstanding the above defect, according to the returns obtained from several charities, it appears that more sick inmates were cured, speaking relatively, in the larger than in less extensive establishments; that surgical patients oftener recovered than medical; that females, treated in the medical division, became convalescent in a greater proportion, than males belonging to the same department; and lastly, that surgical patients, of the male sex, appeared to recover from their various maladies in smaller numbers, than female inmates similarly circumstanced.

Statistics of St. Thomas's Hospital. Believing that it may prove interesting to my readers, I here offer a few general remarks, respecting the principal occurrences met with in one extensive metropolitan hospital. I am induced to do so, because numerous interesting pages have been recently dedicated, in the London Journal of Medicine, to the illustration of various important subjects connected with these establishments. I select St. Thomas's—one of the oldest

and most magnificent institutions of the kind in the metropolis,—and within whose wards 4,239 in-patients were admitted during the year 1850. These were not re-admissions, but separate individuals; as the system of nominal re-registration of the same patient is entirely excluded from the following statistical returns; which were obtained through the kindness of an influential official friend. In reference to the practically useful subject of hospital statistics, it farther affords me much satisfaction to state, that effective measures are now being taken to obtain an ample statement of all the principal points of interest connected with the numerous cases of disease treated, during the current year, at this hospital, besides the results obtained. This report, when completed, will doubtless prove creditable to the managing authorities, as well as beneficial to the entire profession; whilst it may become a good example for imitation in other quarters.

To shew the nature of the diseases which proved fatal in this charity last year, I would now direct special attention to the subjoined report, enumerating the causes of death in the 270 fatal cases recorded at St. Thomas's Hospital during 1850.

Abscess 6	Dropsy 2	Paralysis 3

Total..... 270

According to the above statement, nearly one-third of the entire mortality was produced by diseases of the respiratory organs; comprising 10 fatal cases of bronchitis, 10 of pneumonia, 6 of affections of the lungs, 3 of laryngitis, and 59 of phthisis; thus making, altogether, 88 deaths by these maladies. Hence, all the facts here recorded, entirely coincide with the observations contained in a previous page, and illustrate the great frequency of pectoral complaints throughout England; whilst they also indicate that consumption does not constitute a cause of exclusion from every general hospital of London, seeing, not less than 59 persons died of phthisis during last year, in this ancient charity; of whom 37 were male, and 22 female patients; whilst 115 left the institution more or less relieved, and four were reported cured.

The following table, respecting the age and social condition of the various individuals who recently died of consumption, in St. Thomas's Hospital, was drawn up from the register kept at this institution, and deserves perusal.

Table of Age and Social Condition of the 59 *Fatal Cases of Phthisis recorded in St. Thomas's Hospital during* 1850.

Thirty-seven Males.						Twenty-two Females.		
Age.	Single.	Married.	Age.	Single.	Married.	Age.	Single.	Married.
						18	2	..
				13	7	19	1	..
21	2	..	40	..	1	20	1	..
23	3	1	41	1	1	21	2	..
25	..	1	42	2	..	23	2	..
26	1	..	43	1	..	25	1	1
27	1	2	44	1	..	26	..	1
30	2	1	47	3	..	28	2	1
31	1	..	49	..	1	30	..	1
32	1	..	53	1	1	31	1	..

38	1	..	64	..	1	37	..	1
39	1	..				44	2	..
						59	..	1
	13	7		23	14		15	7

From the above figures it appears, that more single persons than married, in both sexes, died of phthisis; there being 38 of the former, to 21 of the latter; whilst about half the whole number, or 29 individuals, had not exceeded their thirtieth year at the period of death. Such peculiarities, especially in reference to age, seem to have been indubitably pronounced amongst female patients, as 15 of the 22 cases did not exceed 30 years of age; and of these 11 were single, with only 4 married women. On the other hand, out of the 37 male patients, not more than 14, or nearly two-fifths, were 30 years of age or under; of whom, 9 were single men, and 5 married. It may hence be fairly inferred, that consumption proves a more serious malady amongst young unmarried women, than among the married. At the same time, the disease seems to prevail also less frequently in the opposite sex similarly circumstanced; as 9 single men attacked, at or under 30 years of age, died from phthisis, in contrast to 5 who were married.

Another point in reference to hospital statistics also deserves notice, the more so as it illustrates, to some extent, the general features of most diseases affecting patients received into these public establishments; I mean the length of time during which sick inmates remained under medical treatment. This is an important question for inquiry; because, if any facts of that kind be correctly ascertained, professional men can, from such tables, confidently deduce inferences respecting the nature, whether acute or otherwise, of the chief complaints treated in the wards of a particular institution. In order briefly to illustrate the point adverted to, I subjoin a classified return of the exact period which all the 270 patients, who died in St. Thomas's Hospital during 1850, remained under medical or surgical treatment. The details it contains seem interesting, and merit examination.

58	30	88		112	70	182	

Looking at the various data contained in this table, and taking the surgical patients in the aggregate, 27 persons, or 30·68 per cent. of the entire number, died under one week's residence in the hospital. Where the period did not exceed four weeks, 59 surgical patients, or 67·04 per cent., are reported to have died within that term. Again, in regard to medical cases, the ratio of mortality averages rather less at similar short periods; 51 deaths, out of the 182, having occurred under one week from the period of entry, which is equal to 28·02 per cent. Where the time of residence was under four weeks, the proportion, in that case, reached 64·83 per cent., seeing 118 out of the whole 182 patients treated by the physicians died before twenty-eight days had elapsed. The proportion of deaths amongst female surgical patients, whose treatment in hospital ranged under four weeks, actually reached a higher amount than amongst surgical male patients: this is shown by the fact, that 22 of the 30 deaths were classed in this category,—giving a ratio of 73·33 per cent; whereas, amongst the 58 male surgical patients who died before they had resided twenty-eight days in hospital, there were only 37 deaths, or 63·96 per hundred. This indicates that the particular maladies, in these cases, were neither so acute nor rapid in their course amongst men as women. The results recorded in medical patients, when residence in hospital did not exceed four weeks, proved, however, somewhat different, if the male inmates were compared with the opposite sex: thus, 76 of the 112

male patients who died during 1850, had not been under medical treatment beyond twenty-eight days,—thus making 68·03 per cent., whilst the number of casualties amongst female medical patients, similarly circumstanced, was 42, being at the rate of 60 per cent. From these facts, it is clearly indicated that diseases usually treated by physicians seem of a severer type, and become more rapidly fatal among men, than in maladies affecting women. Although the surgical cases ending fatally at St. Thomas's, were less numerous than the medical, a larger proportion of the former class remained longer in hospital before the fatal termination, than prevailed amongst the other division, where disease likewise terminated in death. Six surgical patients out of 88 had resided upwards of six months before death, whereas, only four individuals amongst the total 182 fatal cases in the medical ward, were under treatment for a similar period. Again, the average number of beds occupied nightly by sick persons, amounted to 446, throughout the whole period referred to in previous pages; whilst five weeks and four days constituted the mean time during which each inmate continued in the establishment.

Besides these general statements,—possessing considerable interest, it is also instructive to remind readers, that the mortality reported amongst surgical patients of every description, treated at St. Thomas's Hospital, ranged about four per hundred, compared with the admissions; contra-distinguished to which, the ratio of persons affected with medical diseases,—also proving fatal, was more than double that amount, or fully ten per cent. if calculated in the same manner; thus explaining several results of an important character, and nearly analogous to those experienced, at almost every other similar medical institution, throughout the metropolis.

24, Brook Street, May 1851.

BIBLIOGRAPHICAL RECORD.

Practical Remarks on the Treatment of Aneurism by Compression with Plates of the Instruments hitherto employed in Dublin, and the recent Improvements by Elastic Pressure. By Jolliffe Tufnell, M.R.I.A., Fellow of the Royal College of Surgeons in Ireland, Surgeon to the City of Dublin Hospital. pp. 154. Dublin : 1851.

In this little work, Mr. Tufnell gives the results obtained in Dublin from the treatment of Aneurism by Compression ; and his conclusions are altogether in favour of the new practice. The number of cases reported to have been treated in Dublin, by compression, from October 1842 to March 1851, is thirty-nine ; and, of these, "thirty have been completely cured. In one, compression was discontinued, the aneurism not increasing subsequently in size ; in two, the ligature was resorted to, and the artery tied, with success ; in three, amputation was necessary, each instance being followed by recovery ; in one case, death ensued from erysipelas ; and two died from coexisting disease of the heart." The author expressly informs us that this summary comprises *all* the cases of aneurism treated by compression in the Irish metropolis ; and that therefore it is untrue to allege that the Dublin surgeons have put forth only the favourable, and concealed the unfavourable, cases ; and Mr. Tufnell tells us, moreover, that, in only *one case* (namely, one in which erysipelas supervened) could death be in any way attributed to compression. Now, in contrasting these results with the records of cases in which the ligature has been employed, the success of the new practice is still more clearly manifested. In the work of Dr. Crisp, for instance, the particulars of one hundred and eighty-eight cases are detailed, of ligature of the artery for popliteal or femoral aneurism ; and of these, thirty-five died from the effects of the operation ; eleven recovered after suffering subsequent amputation ; two recovered after sloughing of the sac ; one recovered after mortification of the toes ; and one after sloughing of the integuments : so that more than the fourth of these cases either terminated fatally, or were maimed for the rest of life. Again, Mr. Phillips has collected one hundred and seventy-one cases of aneurism affecting the lower arteries which were submitted to the ligature ; of these, fifty-seven, or one in three, were unsuccessful ; and all these patients died, except two, not of the disease, but of the operation. The third table is afforded by Mr. Norris, who gives the details of one hundred and seventy-seven cases where the operation was performed. Of these, thirty-eight died from the effects of the operation ; six recovered after subsequent amputation ; ten recovered after suppuration of the sac ; and two after gangrene of the foot,—making nearly one out of every three cases, which either terminated fatally, or were, to a certain extent, maimed for the rest of their lives. This evidence is undoubtedly very strong ; and we cannot wonder at the stress which is laid upon it by Mr. Tufnell.

The author very justly remarks, that there is really no difference between the mode of cure by the ligature, and that performed by compression ; for in each instance the current of blood is arrested, and the impulse of the heart no longer communicated to the sac of the aneurism ; and he maintains that compression is equally efficacious with the ligature, when the former is *properly* and *cautiously* applied.

In answer to the objection, that the cure by compression is prolonged and tedious, Mr. Tufnell admits that twenty-five days may, perhaps, be granted as the period for the treatment ; but he argues that the operation by ligature requires, on the average, nearly an equal space of time. Thus, from the moment of the patient's admission into the hospital, until he is placed

upon the operating-table, a week may be allowed. Sixteen days may be taken as the usual period between the application of the ligature and its separation; and five days more may be granted for closure of the wound, and cicatrization; thus making the time quite as long as in the cure by compression. But, in many cases, the cure by compression occupies a much less time; thus, in certain instances adduced by Mr. Tufnell, the process of cure occupied only *twenty-eight hours* on the average; and, in one case, only *seven hours and a half* were required for total solidification of the contents of the sac, and in a very brief period the patient was again at his usual occupation. In another case, a femoral aneurism was solidified in thirty-three hours. Ten days after, the man left the hospital; and *he was married, and danced at his own wedding, within three weeks from the day that pressure was first applied.*

The instruments which have been, and are now used, for compressing the artery, are described in the work before us; and their form is figured in several plates in the course of the volume. It is impossible to convey, in words, any accurate idea of the apparatus employed by Mr. Tufnell; suffice it to say, that it is sufficiently simple, and that without compressing the limb itself, a pad is made to press precisely upon the artery by turning a screw. The elastic force of vulcanized India-rubber is happily employed to supersede the former methods of pressure by metallic unyielding materials; and Mr. Tufnell justly lays great stress upon the importance of this improvement.

The previous treatment of the patient demands notice; and Mr. Tufnell recommends, in the case of a hyperæmic muscular subject, that the action of the heart should be reduced by restricted diet, purgatives, venæsection, and sometimes digitalis; but in an anæmic weakly patient, that a tonic plan should be adopted. The patient having been thus prepared, the apparatus is adjusted to the groin, and the long screw of the instrument is directed obliquely upwards *over the femoral artery* as it passes below Poupart's ligament, and *against* the pubic bone. "This spot", says Mr. Tufnell, "of all in the lower extremity, is the one most suited for compression. Here no nerve is in close apposition to the artery, and the vein is easily avoided by care. Being also superior to the profunda, it is the most fitting point for compression, and effectually arresting the circulation, when employed in those cases of popliteal disease, where symptoms of burning pain in the joint indicate that the aneurism has its origin from the surface of the artery nearest to it, and when the circulation should consequently be diminished as speedily as possible, and to the utmost degree." The pad being placed in position, looking backwards and upwards to the pubis, is to be brought, by the screw, in contact with the skin; then the elastic force is made to bear upon the vessel, and the pressure is to be continued until the pulsation in the tumour is completely checked *to the touch.* Two or three hours will then probably elapse before the patient feels annoyance from the pad, but Mr. Tufnell recommends that the surgeon should not wait until the patient complains of pain, but that, as soon as uneasiness is felt, another apparatus, fitted for compressing the artery in the thigh, and which should be previously loosely applied, should be brought into operation. By these means the circulation is completely arrested. Mr. Tufnell gives the following rule on this point: "Make your command over the circulation complete, but with the minimum amount of pressure by which this object can be gained." In irritable constitutions, where the patient is intolerant of the pain caused by compression, an anodyne draught may be administered. A very good instance of the beneficial effect of anodynes is given in a case occurring in the practice of Dr. Banin. The man had been four days under treatment, and for three nights had not slept, although full opiates had been employed. The instruments, therefore, were loosened, and the man almost immediately fell asleep; but the resident pupil in attendance seized the opportunity of

placing Dr. Carte's instrument upon the artery without waking the patient; and at the end of six hours all pulsation had ceased in the tumour, and it never returned.

Such is an outline of the treatment of aneurism, by compression, practised and recommended by Mr. Tufnell; and we cannot but remark that the results, given in this little volume, have impressed us with a very favourable opinion of this plan of proceeding; and we shall rejoice to find that the success of the system in this country is equal to that which has been achieved by our surgical brethren on the other side of the Irish channel.

Observations on the Diseases of the Rectum. By T. B. Curling, F.R.S., Surgeon to, and Lecturer on Surgery at, the London Hospital. Post 8vo. pp. 123. London: 1851.

Mr. Curling has already earned an excellent reputation as a practical surgeon; and the work before us is well calculated to sustain him in the opinion of the profession. It has unfortunately happened that, with a few honourable exceptions, the rectum has been made a sort of preserve for the especial benefit of gentlemen of the quackish persuasion:—and well stocked has it been with game! There was a story current some years ago of a certain practitioner, in the West of England, who deluded every patient into the belief that he, or she, had stricture of the rectum, and that his gigantic bougie alone could cure them. A certain damsel, daughter of a gallant colonel, consulted Mr. H—— for some trifling dyspeptic ailment, and was speedily informed that she had a formidable disease—in fact, a stricture of the rectum, for which a special course of treatment would be necessary. Shocked, and distressed beyond measure, the young lady hurried home, and communicated the intelligence to her mama. Early on the following morning the colonel was seen, armed with a stout horse-whip, knocking at the door of Mr. H.; but in about half an hour he was observed to leave with a very crest-fallen and nervous air. The fact came out, that the doctor had persuaded Colonel —— *that he too had stricture of the rectum!*

The first object worthy of notice in the work before us, is a very useful speculum invented by the author. It is of a conical form, with a wide gap in the side, extending nearly to the extremity; and fitted with a moveable ebony plug, having a metal plate which perfectly closes the aperture. We consider this extremely well adapted for making examinations of the lower bowel; and by its assistance the true nature of many obscure and troublesome cases may be ascertained, and measures directed accordingly.

Mr. Curling considers chloroform to be a valuable auxiliary in the treatment of diseases of the rectum. "Under its influence the irritable sphincter relaxes, and a complete view can be had of the seat of disease in cases where pain and spasm would otherwise offer almost insuperable obstacles to a satisfactory exploration" (p. 4).

To that painful affection commonly called a *fissure* of the rectum, Mr. Curling applies the name of irritable ulcer. The usual seat of this is in the pouches of mucous membrane, just within the external sphincter. The appearance of a fissure is, in fact, delusive; for it is a superficial oval ulcer, exquisitely sensitive, and giving rise to the most distressing suffering. This is much more common in women than in men. It is seen with difficulty, on account of the spasm which firmly closes the orifice. Chloroform is here invaluable; and with its aid not only can the disease be satisfactorily examined, but easily cured. The treatment necessary is a longitudinal incision through the centre of the ulcer, including the sphincter muscle; by which means this, the great source of mischief, is placed at rest, and the ulcer heals. The healing process may often be promoted by coating a plug of lint with the following application; ℞ Liquor plumbi diacetatis ʒj, confec. rosæ ʒj. M. The plug smeared with this ointment is dipped in sweet oil, and then applied to the part.

As an application to sensitive ulcers of the rectum, Mr. Curling strongly recommends the following ointment, which is also useful in painful affections generally. ℞ Chloroformyli ʒi,—ʒij ; zinci oxydi ʒss ; olei olivæ ʒj ; cerat. cetacei ʒiv. M. Ft. unguentum.

A very clear description is given of the nature of those troublesome companions, *hemorrhoids*, which, says Mr. Curling, "rarely occur before puberty, and which but few persons in after-life altogether escape". In external piles, if palliative treatment does not avail, excision is recommended. In cases of internal piles, the author speaks highly of the benefit derived from a lavement of half a pint of cold spring water thrown into the rectum every morning after breakfast. As an aperient, the lenitive electuary, with sulphur, or the bitartrate of potass at bed-time, is very serviceable. If in these cases the piles are a source of great annoyance, operative proceedings must be had recourse to, and the ligature is strongly recommended. A dose of castor-oil, he says, should be given eight hours before the time fixed for the operation, and a pint of warm water should be thrown up shortly before the surgeon's arrival. When the fluid is discharged the piles will descend. If chloroform be given, the patient should be placed on the side with the thighs raised ; otherwise, the patient should lean over a table with the nates separated. The growth should then be drawn out with a volsellem, and tied tightly around the base, or strangulated with a needle and ligatures. It is well to bear in mind that retention of urine is occasionally the result of this operation. In a case which recently fell under our own observation, a catheter was required night and morning for a fortnight.

The following is the summing up of Mr. Curling's opinions relative to the tying of piles.

"The extirpation of hemorrhoids by ligature is both an effectual and a safe mode of treatment, and the use of chloroform removes almost entirely the pain attending it. Those adverse to the plan have magnified the risks and sufferings, and have spoken of phlebitis and tetanus, and diffuse inflammation, followed by sloughing, as common occurrences after the operation. No fatal case has come under my notice, either in public or private practice. .... An unfortunate result from the application of ligatures to piles is entirely exceptional : and, with common precaution, this proceeding must be regarded as safe as any operation in surgery" (p. 41).

The treatment of hemorrhoidal tumours by strong nitric acid is sometimes very appropriate. The conditions to be observed with regard to the operation have been well laid down by Mr. Henry Lee of King's College Hospital.[1]

Mr. Curling's observations on fistula in ano, chronic ulceration, stricture, and cancer of the rectum, are all based on sound judgment and extensive experience. The work, indeed, bears the stamp of these high recommendations, and contains much sound information respecting a painful, often intractable, and always very distressing class of diseases.

Apology for the Microscope ; being the Introductory Lecture to the First Course on Microscopic Anatomy and Pathology, delivered in the Theatre of the Original School of Medicine, Dublin. By Robert D. Lyons, M.B., T.C.D., L.R.C.S.I. pp. 45. Dublin : 1851.

We should have imagined that the microscope needed no apology from a teacher of the medical faculty in the Irish metropolis ; but we regret to learn, from a perusal of this lecture, that microscopical research is by no means, at present, a favorite pursuit with either professors or students in the sister island. This production of Dr. Lyons is a very eloquent appeal to his professional brethren in behalf of a branch of investigation which, it appears, they have too long neglected ; and we shall be happy to learn that

[1] London Journal of Medicine, vol. for 1849, p. 92, quoted from *Medical Gazette*.

his exertions are crowned with success, and that the reproach is thus removed from the Irish school. The history of microscopical discovery is very luminously described in the lecture before us, and due honour is awarded to the labourers in this fertile and inexhaustible field. We sincerely wish Dr. Lyons the success which he merits, and hope hereafter to see his name recorded among the successful cultivators of this fascinating department of natural history.

Phthisis and the Stethoscope. A concise Practical Guide to the Physical Diagnosis of Consumption. By Richard Payne Cotton, M.D., Assistant-Physician to the Hospital for Consumption and Diseases of the Chest. pp. 97. London: 1851.

The present work—already favourably noticed in this Journal—appeared in the form of six lectures delivered at the Brompton Hospital, and published in the *Medical Gazette*. The author modestly announces that the matter, which his pages contain, "is not intended to supersede any of the larger works upon physical diagnosis, but is merely designed for the use of those whose professional duties require that such matters should be studied, rather in abstract than in detail".

In the first chapter the general characters of the healthy chest are described; the physical symptoms of the first stage of tubercle are detailed in the second, third, and fourth chapters; the third chapter is occupied by the signs attending the second stage of phthisis; and the last chapter is devoted to the consideration of the third stage of the disease.

The whole work is what it professes to be, a concise practical treatise on the insidious and fatal disease of which it treats. The author has had extensive opportunities for observing the symptoms and progress of phthisis; and the results of some of his investigations are now instructively communicated to the profession.

Conspectus Medicinæ Theoreticæ, capita quadraginta tria universa complectens, ad Usum Academicum. Auctore Jacobo Gregory, M.D., olim Med. Theor. nuper Med. Pract. in Acad. Edin. Prof. Editio undecima, omni parte perfecta, prioribus emendatior. pp. 433. Edinburgi: 1850.

Criticism upon a work so well known and so highly appreciated as Gregory's Conspectus is quite superfluous; it is sufficient to welcome the eleventh edition with the remark, that the work, in the elegance of its Latinity, the extent of its learning, and the soundness of its practical views, is one of the most useful and most important of the modern classics. The present edition contains nothing more than the Latin text. It is well printed and carefully edited.

The Book of Almanacs: with an Index of Reference, by which the Almanac may be found for every year (whether in Old or New Style) from any Epoch, Ancient or Modern, up to A.D. 2000. Compiled by Augustus de Morgan, Sec. R.S.A., Professor of Mathematics in University College. London: 1851.

This is a most interesting, and a most extraordinary work. It is correctly described in the title-page, which we have transcribed.

PRACTICE OF MEDICINE AND PATHOLOGY.

ILLUSTRATIONS OF FATTY DEGENERATION OF THE HEART: CASES OF THE REVEREND DR. CHALMERS AND DR. ABERCROMBIE.

Dr. Begbie in a valuable paper on this subject, in the *Edinburgh Monthly Journal* for March 1851, relates the following particulars of the last illness of the Rev. Dr. Chalmers, and of Dr. Abercrombie, and the appearances observed after death. They will be read with much interest, as well on account of the nature of the fatal affection, as the great and deserved celebrity of its victims, and the close resemblance presented, in many points, by the symptoms.[1] We have considerably abridged Dr. Begbie's essay.

Case I. Dr. Chalmers died in his sixty-eighth year; and was often seen by Dr. Begbie during the last fifteen years of his life. To a mind of the highest order, and of wondrous energy, he united a hale and vigorous, a manly and robust, frame of body; and he spared no exertion, either mental or physical, in endeavouring to benefit his fellow-men. He was hardly ever incapacitated by infirmity, or loss of health, in prosecuting his enterprises; and in them up to his latest hour, he toiled, and spent his energies and his strength. These things show, that the fatal disease which lurked within, which was progressive in its nature, and probably of long-standing, could neither have produced serious uneasiness, nor proclaimed its presence by any unequivocal signs. One alarming illness, it is true, overtook him some years before his death; and though we can now connect that first indication of disordered circulation with a well-grounded suspicion of commencing cardiac disease, yet his perfect recovery, and the absence ever afterwards of any similar manifestation, were calculated to repress all apprehension of danger. The attack happened in the winter of 1834, thirteen years before he died. It was thus:—He was engaged in the early part of the day in attending a meeting of the Presbytery of Edinburgh, and had taken an interest and a share in the discussions. When returning home with a friend, he was suddenly seized, in the street, with loss of power and diminished sensation over the right side; the arm and leg being chiefly affected. He felt, to use his own description, as if instantaneously a large weight of books had been placed in one of the pockets of his great-coat, and had thrown him entirely to one side. He would have fallen to the ground, but his friend supported him, and had him conveyed to a neighbouring house, and, after a little, to his own home, whence Dr. Begbie was called to see him immediately on his arrival. Dr. Begbie found him in bed, calm, but impressed with the conviction that he was struck down by a formidable disease. His mind was quite entire; nor did it suffer in the least during his illness. His speech was somewhat affected, and his articulation was imperfect. The muscles of the right side of the face were partially paralysed; those of the arm and leg decidedly so. Sensation over the whole of the right side was much impaired, and particularly over the thigh and leg, which he continued to beat firmly with the left hand, in the hope, as he said, of recalling sensation. The face was pale, the skin cool, the pulse soft and frequent. There was no headache or giddiness, nor any pain or uneasiness beyond what has been described. The treatment pursued was moderate bleeding, purging, diaphoretics, rest, and quiet. Under this, he daily improved; sensation and motion were gradually restored, and, after a few weeks' confinement, he returned to his avocations,

[1] An excellent Life of Dr. Chalmers is in course of publication by his accomplished son-in-law the Reverend Dr. Hanna, of Edinburgh: a Biography of Dr. Abercrombie is still a desideratum.

and engaged as heartily and laboriously as ever in his literary and professional duties.[1]

Important events in the church by and bye occupied his mind; and negotiations, connected therewith, pressed upon his attention year after year. He was found equal to the time. Perhaps these matters told upon him. He was now approaching his grand climacteric, yet he was firm and robust. With accumulating years came a disposition to obesity, and also the pallid and somewhat sickly look of fading health. Yet he seldom complained; or, if indisposed, it was only by some trivial ailment arising from indigestion. He was sometimes sick at stomach, but he was never faint, nor ever swooned away. He sometimes manifested a sense of exhaustion; but even then he could, when occasion required, rouse himself to great mental or bodily efforts. He had no præcordial pain, nor distress in breathing; no palpitation of the heart, nor intermission of the pulse. He ascended heights with wonderful facility; he slept on either side, and his rest was calm and refreshing. Had any symptoms at this time called for exploration of the chest, it might perhaps have been discovered that the impulse of the heart was feeble and indistinct; and that its first sound was imperfectly heard: and by conjoining these signs with the soft, but not feeble pulse, the pallid countenance, the time of life, and the ready disposition to take on fat, degeneration of the muscular tissue might have been supposed to have already made progress. But this could only have been a reasonable conjecture.

Early in May 1847, when in the enjoyment of his usual health, Dr. Chalmers repaired to London to give evidence before a committee of the House of Commons. He preached on three successive Sundays with all the eloquence and energy of former days; and during the week was much engaged with the business of the committee, shewing no symptoms of serious illness. On his way home, he visited some relatives in the south of England, and reached Edinburgh at the close of the month, in excellent health and spirits. He attended public worship on Sunday the 30th, and met his family in the usual exercises of the day. He retired to rest at an early hour; being engaged on the following day to read to the General Assembly a report, which had occupied much of his time and thoughts. On Monday the 31st, not having responded to the usual call in the morning, his chamber was entered, and he was found cold and lifeless. Dr. Begbie saw the body before it was disturbed. It lay in the half-recumbent posture; the head supported by pillows; the arms folded on the breast. The bed-clothes were scarcely disordered; and on them rested a basin, which had received the contents of the stomach. He had been overtaken by sickness and vomiting; but at what hour it is impossible to fix. This last circumstance of vomiting, coupled with his former paralytic attack, rendered it very probable that some cerebral lesion was the cause of death.

Necropsy. The examination of the body was conducted by Dr. Hughes Bennett on the evening of the following day, the 1st of June. The weather was unusually sultry.

External Appearances.. The body was fat and robust; the head large; the chest broad. Putrefaction had taken place to a considerable extent. The features were swollen, bloated, and of a purple colour. The neck and upper part of the chest were of a green colour, and emphysematous.

Head. The integuments of the scalp were unusually thick; on dividing them, fluid blood oozed from their cut surfaces. The cranium was very thick and dense. It was every where fully a quarter of an inch thick, and in some places three-eighths of an inch; it was unusually weighty. The two surfaces of the arachnoid membrane were pretty firmly united superiorly, and were lacerated on separating the brain. The angle where the falx turns

[1] During the month of June following, Dr. Chalmers apprehended a renewal of similar symptoms; but the threatened attack passed away, and never returned.

down was crossed on both sides, from before backwards, by firm bands of chronic lymph and fibrous tissue, some of which were nearly an inch long. A calcareous deposit, the size of a pea, was situated about the centre of the falx. The cerebral arachnoid was thickened, and perfectly opaque in the immediate neighbourhood of some of the larger meningeal vessels, presenting, on removal, a white glistening appearance; it was easily removed from the cerebral convolutions, which, superiorly, were large, and the sulci deep. The brain weighed fifty-three ounces avoirdupois. Its structure was everywhere healthy. The choroid plexus contained small groups of simple cysts. A large quantity of fluid blood came from the divided arteries at the base of the brain.

Chest. Each lung was slightly adherent at its apex by one chronic adhesion of limited extent. On the left side, the pleura at the seat of adhesion was thickened, over an extent the size of a shilling, about one-eighth of an inch. The serous surfaces and lungs were otherwise perfectly healthy. The pericardium was healthy. The heart was flabby, and unusually soft. The coronary artery was loaded with calcareous deposit, much contracted, and in one place obliterated, presenting considerable resistance to the knife. The heart contained no blood; its endocardial lining was deeply stained of a reddish and purple colour; the valves were healthy. The walls of the left ventricle, towards the base, and at their thickest part, were only half an inch thick; at the apex, in one place, only one-eighth of an inch thick; the surface of the section showed that the muscular substance had undergone fatty degeneration. In some parts of the ventricle, half the substance was completely fatty; in other parts, nearly its whole thickness was fatty, with a line of muscular substance, one-sixteenth of an inch thick, only remaining. Even this muscular substance was of a pale and yellowish colour. The right ventricle was unusually thin, and superiorly was so soft, that it broke down under the finger, and could be torn like a soft pulpy substance. Everywhere the substance of the organ was soft and friable.

Abdomen. The liver was small, of a dirty olive-green colour throughout. The gall-bladder was distended with yellow fluid bile. The spleen was small; on section, it presented a black colour. The omentum and subperitoneal cellular tissue were greatly loaded with fat. The kidneys were imbedded in a surrounding mass of fat an inch thick, they were soft and flabby, of a dark mahogany colour, but in texture healthy. The stomach, internally towards the larger curvature, was of a greenish hue, with slight extravasation of blood below the epithelium. The intestines were healthy.

Microscopic Examination. The substance of the heart throughout consisted of fatty granules. The muscular fasciculi could scarcely be seen, although here and there traces of the longitudinal fibrillæ could be observed. No transverse striæ were anywhere visible.

Dr. Hughes Bennett suggests, as the probable cause of the want of blood in the heart, that it had drained away, in its putrid state, from the divided cerebral vessels, during the examination of the contents of the cranium.

Case II. Dr. Abercrombie died in his sixty-fifth year. He enjoyed, during a long series of years, uninterrupted health. In the winter of 1841, three years before his death, in driving to a professional engagement, he was suddenly seized with loss of power and impaired sensation over the left side, but without loss of consciousness or any affection of speech. He immediately returned home, and gave orders for the abstraction of blood by cupping. Dr. Hunter, who was called to him, found him under great anxiety, complaining of præcordial uneasiness, and slight headache, with frequent sighing, cold skin, and pallid countenance. The pulse was frequent and small at first, but, after a while, it subsided in frequency and rose in strength. Blood was taken from the temple and arm to a large extent, and active purging was pursued by the patient's desire. The details of this attack have been given

elsewhere. It was Dr. Abercrombie's decided impression that his illness was paralysis, connected with cerebral disease, and that impaired mental and bodily power would be the lasting consequences. It certainly never occurred to any of his medical advisers to connect the symptoms with deranged circulation, arising from a damaged heart. He did complain of præcordial uneasiness—it never amounted to pain—and of something more than uneasiness in the left arm and shoulder, and at the base of the scapula; but the circulation was regular, though feeble, and the feebleness might readily have been accounted for by the active measures which he himself employed, and the scanty fare to which he subjected himself,—treatment which no long time afterwards was found to have been entirely misplaced.

Dr. Abercrombie recovered from this attack; and in the course of a few weeks was able to resume his professional duties. He continued pallid, however, and had somewhat the air of an invalid, but his mind was as active and intelligent as ever. Previous to this attack, he had become rather corpulent and fat. He never had any threatening of return of similar symptoms during the three succeeding years, nor any indication of latent disease, beyond what was remarked by Dr. Alison, when, in accompanying him up stairs a few days before his death, he observed that he was breathless. On Thursday, the 14th of November, 1844, Dr. Abercrombie was in his usual health; he engaged with his family in the devotional duties of the morning; he breakfasted with appetite, and, after visiting a domestic in the family, he retired to the water-closet. He was there sufficient time to justify the suspicion that some illness had overtaken him; and, on opening the door, he was found extended on the floor in the arms of death. A few convulsive sobs were heard,—and life departed.

Necropsy. The body was examined by Mr. J. Goodsir, who gave the following account of the morbid appearanes.

Head. The skull-cap was thick. The crista galli, the posterior clinoid processes, and the bones of the head generally, were powerfully developed. The brain was softer than might have been expected at the time of the examination (fifty hours after death). There were no traces of old or recent effusions of blood. The internal carotid, the circle of Willis, and all the arteries of the organ were studded with much atheromatous deposit; and the internal carotids, at their last curve, were slightly dilated. The brain was of great size, and weighed sixty-three ounces avoirdupois. The ventricles were capacious, without an increased amount of serum, which appeared to correspond to the great size of the cavities.

Heart. The pericardium contained a large clot of blood, enclosing the heart as a mould. On the posterior surface of the left ventricle, two-thirds from its base, and about an inch and a half from the septum, there was a fissure or rent, a quarter of an inch long, in the direction of the fibres of the ventricle, with ragged and ecchymotic edges. Towards this fissure, a considerable branch of the left coronary artery passed, but did not enter into it. In the fissure the ruptured orifice of a vein was visible, and a bristle introduced into it passed on towards the base of the ventricle, and appeared on the cut surface of the posterior wall of the ventricle, made on opening the heart. In the neighbourhood of the rupture two irregular ecchymotic spots were situated, through which passed branches of the coronary artery. These spots consisted of effused blood, but their connexion with ruptured vessels could not be distinctly made out. The serous membrane over them was quite entire. Both coronary arteries were much dilated as they passed off from the aorta. Throughout their course they contained in their walls much atheromatous matter, but were not ossified. The aorta and its semilunar valves also contained a considerable amount of the same deposit, but the former was not enlarged. The heart was slightly enlarged and dilated, rather loaded with fat, and remarkably soft, as if from interrupted nutrition. All the cavities of the heart were found empty. There

were extensive adhesions of the right pulmonary and costal pleuræ. The other viscera were healthy.

Mr. J. Goodsir made a microscopic examination subsequently to the drawing up of his report of the inspection of the body, from which it appeared, that the muscular fibres of the ruptured portion of the ventricle (alone examined) had undergone the fatty degeneration, being here and there interspersed with fatty granules, generally in transverse rows,—and that there were masses of fat cells or globules at intervals,—while some of the fibres were nearly empty.[1]

Remarks. Dr. Abercrombie and Dr. Chalmers were both of the age when the tendency to fatty degeneration has been shewn to be most prevalent. Among 83 cases collected by Dr. R. Quain,[2] death occurred in 14 between the ages of 50 and 60 ; in 18, between 60 and 70 ; and in 14, it occurred between 70 and 80. These eminent men had also indicated a proclivity to the disease by a constitutional tendency to take on fat, and in doing so, to assume the pallid and sickly look of diseased nutrition,—facts which have been remarked by many observers. They terminated their lives in the manner most common to those who suffer from it, the one by rupture of the heart, the other in syncope. Of Dr. R. Quain's 83 cases, 28 died in the former, and 26 in the latter mode.

Mr. Paget has remarked, that the principal character which all the cases of fatty degeneration of the heart seem to present, is, that they who labour under this disease are fit enough for all the ordinary events of calm and quiet life, but are wholly unable to resist the storm of a sickness, an accident, or an operation. There may be much general truth in the statement; and in the two cases just recorded, it is worthy of remark, that up to the hour of death the individuals were actively engaged in the labours of most arduous professions, and were overtaken, as in other recorded instances of this particular lesion :—the one, it is believed, by the act of vomiting ; the other, by an effort at stool.

Dr. R. Quain, in referring to the fact that fatty degeneration of the heart is said to be frequently found after death, where its existence had not been suspected during life, has expressed the opinion, that such cases would not often be met with, if a full inquiry could be made into their symptoms; and then goes on to remark :—" I feel the truth of this observation, more particularly in those cases which occur in the progress of advancing life, when, whilst the system generally keeps up its powers tolerably well, the heart suffers from some local cause, such as diseased coronary vessels. In those cases the balance between the system and heart is lost, and phenomena as clear and as pointed as any that can indicate the nature and seat of disease are developed."

What reply do the two cases now related make to this unqualified statement ? The subjects of these cases had made progress in advancing life. They expired in a sudden and unexpected manner; and examination after death disclosed the hidden cause, in the peculiar lesion of the heart, accompanied by the morbid condition of its vessels, to which Dr. Quain refers; yet, during life, neither of them exhibited any of those clear and pointed phenomena to which he alludes. The testimony of Dr. Abercrombie is peculiarly valuable in relation to this point; he never acknowledged, and probably never felt, any of those symptoms of degeneration of the heart indicated by

---

[1] For more ample details of Dr. Abercrombie's case, vide an interesting memoir in the *Edinburgh Monthly Journal* for Dec. 1844, and a similar article in the *Edinburgh Med. and Surg. Journal* for January 1845.

[2] Quain, Dr. Richard, in *Transactions of the Royal Med. and Chir. Society*, vol. xxxiii, p. 121. London: 1850; also London Journal of Medicine, July 1850, p. 705.

Dr. R. Quain,—symptoms which seem more intimately connected with those other morbid conditions and lesions of the organ which usually coexist with fatty degeneration.

Let us shortly inquire what those signs, general and physical, are, which are said to denote this degeneration of the heart, with the view of discovering any modification of their features in the history of the cases now under consideration.

1. First in order, have been mentioned symptoms of cerebral congestion, such as *giddiness*, *drowsiness*, and *coma*. No symptoms of this kind were at any time witnessed; and though manifestations of interrupted circulation in the brain might have been expected to flow from the want of muscular power in the heart to propel the blood brought by the veins from the head; yet, if we except the attacks above described, there were no symptoms which pointed to early changes in the muscular fibres of the heart. It is difficult to account for the exemption from future attacks which both patients experienced, the one during the three, the other during the thirteen, last years of life.

The occasional occurrence of apoplexy and palsy, in connexion with fatty degeneration of the heart, may more readily be traced to other morbid conditions of the organ, which coexist with that particular degeneration, than to the degeneration itself, such as hypertrophy of the left, and dilatation of the right, ventricle; more especially when these again are associated with disease of the blood-vessels of the brain.

2. *Faintness* and *syncope* are next recorded as symptomatic of fatty degeneration of the heart; but they were not observed in either of the cases now related, though there is reason to believe, in the absence of other causes to account for death, that a fatal syncope at last overtook the distinguished individual who is the subject of the first sketch. But syncope is not an uncommon symptom of other affections of the heart, and may naturally be expected to arise where the left chambers of the organ are deficient in muscular power in transmitting the blood to the brain, whatever may be the immediate cause of this loss of power, whether the growth of fat upon the organ, the degeneration of its muscular tissue, or the dilatation and thinning of its walls from other morbid changes. It has been observed, that the peculiar degeneration we are now considering, is at times confined to one ventricle, and at other times to its fellow, and that often both are equally affected. May not the prevalence of head-symptoms at one time, and of syncope and faintness at another, be accounted for by the part of the organ implicated? When the right ventricle is softened and wasted, comatose symptoms may be looked for, in consequence of the interruption to the free discharge of blood *from* the brain: when the left ventricle suffers, then syncope may be expected, from the want of full and free circulation *within* the head; while, when the chambers of both sides equally participate in the degeneration, the circulation may be feeble and slow; but it will not be liable to those disturbances which are likely to arise from the balance of power being lost between the two sides of the heart.

3. *Shortness of breathing* is a symptom frequently observed in those labouring under fatty heart; but it was not present in either of our cases. It has been already remarked, that Dr. Chalmers continued to the last to ascend heights with wonderful facility; and Dr. Hunter informs me, on the best authority, that Dr. Abercrombie, during the autumn which preceded his death, was in the habit of ascending the hills in the neighbourhood of his summer residence, without experiencing any difficulty of breathing; and all, who were accustomed to meet him professionally, must remember the quick and alert manner in which he mounted to the bed-room floor, in cases of sickness. It has, however, been noticed, that an experienced observer had, on one occasion, and that a few days before his death, remarked that, in ascending the steps of his own house, Dr. Abercrombie was breathless. It

was the first and the only remark of the kind; and perhaps it is right to mention, that it was made at a time when Dr. Abercrombie was recovering from a bronchial attack, which had confined him for a day or two to the house. But we must expect dyspnœa in cases of softened and degenerated hearts; it is not, however, a constant symptom, and, even when present, may be found to be connected with other coexisting hindrances to the free circulation through the lungs.

4. *Præcordial pain* is another of the characteristic symptoms of this disease of the heart; and certainly has been acknowledged by many who have fallen victims to it. But it is a remarkable fact, that in the case both of Dr. Abercrombie and of Dr. Chalmers it was entirely wanting. The former was sensitively alive to every morbid feeling; the latter was not indifferent to suffering, but, with the exception of the præcordial uneasiness which for several days affected Dr. Abercrombie during the illness which we have referred to as occurring three years before his death, he was never known to complain of pain, nor had he at any time the least suspicion that he was the subject of cardiac disease; while, in the instance of Dr. Chalmers, I cannot call to recollection the smallest complaint of pain, anxiety, or distress in the region of the heart. Both had the coronary vessels extensively diseased; but neither suffered the symptoms of angina pectoris, unless it were in the moments which preceded dissolution.

5. *Functional derangement of the liver and chylopoietic organs* has been noticed as a constant attendant on this form of heart disease. Hasse informs us that, so far from being a merely local morbid condition, as some pathologists believe, it is the result of various affections in other organs; and, though not manifested by any specific local symptoms, its presence may, nevertheless, be inferred with tolerable certainty from collective symptoms referable to other parts of the body. Thus he mentions that, in functional disturbance of the larger organs of secretion, and especially of those engaged in the elaboration of venous blood, we meet with fatty encumbrance of the heart in its second stage; the anormal condition being then conjoined with other changes, all dependent more or less directly upon hepatic or pulmonary disease, or, at any rate, indicative of venous plethora.[1] Various morbid conditions of the liver are noticed among the collected cases of Dr. R. Quain; and in the instance of Dr. Chalmers this part was also found diseased. It was the organ, especially in his later years, which was most readily disturbed, being quickly influenced by errors in diet, or by stimulating beverages; hence he was led to abandon the use of wine and fermented liquors, and to confine myself entirely to water. An interesting fact in his history, which he communicated to Dr. Begbie, bears upon this subject,—namely, that the continued use, for a few weeks together, of a mixture of spirits, water, and sugar [*toddy* ?], was invariably attended with a manifest increase of fat, which subsided on the disuse of the stimulating drink. This fact, taken in connexion with the circumstance of fatty heart being frequently found in those addicted to the free use of spirits, may lead to the suggestion of prophylactic measures in the case of those who appear to labour under that disease.

6. *The state of the pulse* cannot be depended upon as a diagnostic mark of fatty heart. In some cases it has been found irregular, in some weak, in others slow; but it is subject to much variety, according to the complications of cardiac disease which concur with this degeneration of the muscular fibre. In both Dr. Abercrombie and Dr. Chalmers the natural pulse was soft and weak; it was never irregular, nor at any time of such a character as to raise any apprehension of organic disease. Hence, in neither case was auscultation employed as a means of discovering the physical signs which

[1] Hasse, Dr. C. E. Pathological Anatomy (Sydenham Society's Translation), p. 169.

are said to belong to fatty degeneration. Admitting, however, the discovery of a feeble impulse, a feeble first sound, and extended præcordial dulness,—signs which the state of the heart after death might have led us to infer existed during life,—still these, when combined with any general signs recognised during a long course of years, could not have led to a distinct and satisfactory diagnosis; while, taken in connexion with the age of the individuals, their pallid complexion, and tendency to obesity, they give room for the conjecture, that the great organ of life in both, was yielding, through the progress of time, to those organic changes which mark the decay of its structure, and foretell the not distant cessation of its long-continued functions.

CANCEROUS TUMOUR OF THE NECK IN A CHILD.

A case of this unusual description is thus related by Dr. Gibb, Physician to the Montreal Dispensary.

Case. On the 14th of February, 1850, Madame F— called upon me for advice about her little boy, aged 5½ years, with a tumour in his neck. His history was as follows: When about three months old he had ascites, with œdema of the arms and chest, which after some time disappeared without treatment. His health continued good until he was two years of age, when he became delicate and sickly. When about three and a half years old, he fell upon the pavement and struck the front part of his chest, fracturing the middle of the sternum, which some time after united, but with angular deformity, the projecting angle being considerable. He was at this time treated by an eminent surgeon, who recommended suspension of the body by the arms, from the steps of a ladder, to correct the deformity, and at the same time put him upon tonic treatment. When about four years of age, a small tumour, less than the size of a marble, was noticed on the right side of the neck, near the angle of the jaw; it commenced slowly to increase, and after the lapse of six months attained the size of the yelk of an egg.

He was treated for it by as many as six or seven physicians, and had taken a large quantity of medicine from each: he took iodine internally as well as locally, which his mother thought reduced the tumour a little, or kept it stationary for a time. It had, however, continued to grow up to the present time, and has assumed a large size. On the 1st of January, 1850, he had an eruption about the face and head, which turned into sores; and on the 14th of February there were some red patches about the face, the remains of the sores.

Symptoms and Appearances. A tumour existed on the right side of the neck, proceeding from the parotidean region, downwards towards the clavicle, and extending in the direction of the shoulder. It approached also the mesian line of the neck, and would appear to encroach slightly upon the larynx, but not extending within the lower jaw. The tumour formed a considerable prominence, and a number of small veins were running in different directions over its surface. On the left side of the neck the external jugular was very prominent; not so on the right side. Three or four small red patches were present on the right cheek and chin; the countenance was pale and flabby; the eyes prominent and full of expression, which, with the shape of the head, denoted precocity of intellect; and the general appearance was what would be at once pronounced by an observer as scrofulous. On examining the tumour, however, we found that it was lobulated, and divided into two portions, a superior and an inferior; the former was partly anterior to the inferior at its lower part, and the latter extended outwards and downwards upon the neck towards the shoulder. The tumour was freely moveable in every direction; the integuments were not at all adherent to its capsule; and the consistency of the tumour was that of scirrhus, as it was impossible to make any impression upon it by firm pressure, from its firm and hard character; and

scarcely any pain was induced. The glands on the opposite side of the neck were not affected, nor were the glands in any other part of the body. The sternum was curved forward, and the chest anteriorly was prominent and rounded ; in other words, pigeon-breasted, said to be produced here by the occurrence of former fracture. The general health appeared to be good. There was no perceptible lesion of any internal organ.

The child had been seen and carefully examined by my friend Dr. Wright, and we coincided in the opinion as to the propriety of removing the tumour by the knife. The parents would not immediately consent to the operation, preferring to get further advice as to the expediency of this treatment.

I will here remark, that an operation was justifiable at this time, from the nature and character of the tumour—its peculiarly fibrous hardness, which was opposed to its being scrofulous ; its great mobility, and superficial situation over the deep cervical fascia ; its circumference being well defined, none of the deeper structures of the neck being either adherent to, or engaged in the diseased mass ; and the patient's health being good, without any internal complication, for after a careful examination of the thoracic and abdominal viscera, no lesion could be detected.

At a later period, however, one of the abdominal viscera became engaged, no doubt owing to the contamination of the circulating fluid by the malignant disease.[1]

On the 28th of February, I again saw the little fellow, and found the tumour very slightly increased in size. He was suffering from diarrhœa, for which I prescribed some powders. The parents had not made up their minds as to what they should do, as they said other gentlemen whom they had seen had declared an operation inadmissible.

On the 5th of March, the tumour appeared to be still further increasing, and spreading in a direction downwards and inwards.

On the 15th of May, for the first time, he began to complain of pain in the abdomen ; and on examination a hard body was felt, roughened or tuberculated on the surface, extending from the superior part of the left lumbar, towards the middle of the umbilical region, and which proved to be hypertrophy of the spleen. The liver was of normal dimensions, and the kidneys were healthy, as the urine presented nothing unusual. From this time to the 28th of June, the tumour kept slowly increasing in size, and extending in a direction further upwards and downwards, becoming more adherent near the angle of the jaw, and pushing the head towards the left side. He suffered at times from spasmodic cough, with occasional fits of dyspnœa, expectoration of frothy mucus, and a dislike to have anything around his neck. He, however, ate well, and slept comfortably.

During the months of July and August, nothing material was noticed in the progress of the case, excepting visible increase in the size of the tumour, and further enlargement of the spleen. He did not suffer from any pain ; but his cough was much more troublesome, requiring special treatment. On the 2nd of September, he complained of pain in his stomach and legs. He was unable to lie on his left side, from a sensation of choking being produced. He at this time also had frequent and severe fits of dyspnœa, almost amounting to suffocation ; he had alternate chills and flushings ; he was still able to sit at the door, although very weak, and was up till within two days of his death. Many of the symptoms mentioned continued to recur, with the addition of œdema of the hands and arms, and dysphagia. On the day previous to his death, he was seized with symptoms of choking, with congestion of the face and neck ; and the dyspnœa was so great, that the surgeon who was called in wanted to perform tracheotomy, which the parents would not consent to.

[1] This fact is supported by the observation of Heller, in his *Pathological Chemistry of Cancer*, where he has shown the contamination of the blood in that disease, and has given a microscopic analysis of the blood in ten cases.

He continued to get worse, and died at half-past seven a.m., on the 19th of September, without a convulsive movement—carphology, however, existing a few hours before death.

The Necropsy was performed on the 20th, thirty-three hours after death, assisted by Drs. Peltier and Fenwick.

External Appearances. Colour of skin almost that of marble, perfectly blanched and smooth; rigor mortis slight in degree; tumour in neck very much sunken, and apparently diminished in bulk; extremities emaciated.

Tumour. On making an incision several inches long through the skin, in the long axis of the tumour, it was found that it was not adherent to it, throughout any part of its circumference. It (the tumour) was moveable, but was firmly bound down to the deep cervical fascia. It was formed from an apparently enlarged gland, with others also enlarged attached to it, like bundles of grapes, and extending upwards under the lower jaw, forwards and inwards, towards the mesial line of the neck, one lobule pressing rather firmly against the middle of the trachea; others extended backwards, and the bulk of them downwards towards the base of the neck and within the clavicle. On carefully dissecting away the greater part of this diseased mass, the attachments posteriorly and below were found very persistent, and required some effort to remove with care. The subclavian vein was pushed forwards, and the inferior part of the tumour lay immediately over the sac of the pleura. The sheath of the common carotid was pressed upon, and on dissecting the base of this tumour, the phrenic nerve seemed to emerge from almost the substance of a part of the tumour itself. The mass, as a whole, weighed about two pounds. On making a section through the centre of the tumour, it was with some difficulty that the scalpel could be made to cut, so hard and fibro-cartilaginous was its nature; the glandular appearance did not exist, but it was replaced by what resembled true scirrhus, both in texture and consistence, and in general appearance. The smaller appendages to this mass were not quite so hard on section, but no tuberculous substance was seen; nor, in fact, did a single gland that was examined present any scrofulous character.

The microscope here proved a great auxiliary in clearing up the true character of the tumour. Portions from the large scirrhus mass presented a well-marked fibrous structure, the fibres partaking of rectilinear arrangement; between these appeared round cells and molecular granules; some of the former were nucleated and some fusiform, not distinctly caudate, but possessing one or more nuclei, with an occasional nucleolus. The fibres were in parts interlaced with one another in one portion under examination, with small nucleated cells in the meshes. There was a little juicy exudation from the section of the tumour, but a very few cells were free on the field of the microscope. The smaller appendages of the large tumour presented nothing marked from the ordinary glandular structure.

Thorax. The angular curvature of the sternum outwards was particularly striking. The lungs, bronchi, and pleuræ were perfectly healthy; three ounces of dark straw-coloured serum were present in the cavity of the right pleura, and about an ounce in that of the left. The pericardium contained two ounces of serum, and was, together with the heart, quite healthy. There were no abnormalities, either in form or texture, in any of the great vessels arising from the heart.

Abdomen. On pushing aside the small intestines, the spleen, enormously enlarged, was presented to view. It was irregularly nodulated, of a mottled crimson colour, with circular white patches scattered on its surface. It was exceedingly hard and resisting to the knife; and a section showed the dark structure of the spleen itself, with white lines scattered throughout, and numerous circular sections of hard tubercles in various parts, varying in size and colour, the largest about half an inch in diameter. Some of these tubercles, under the microscope, showed granules free and in clusters; fat

globules, large circular cells containing granules, very much resembling the compound granular corpuscle of Hughes Bennett, and most probably the result of inflammation ; and a number of melanotic granules, but no globules. The spleen weighed two pounds and a half. The liver was healthy, but of a sea-green colour, from decomposition ; there were about four white spots scattered over its surface, showing the existence of tubercles, the size of small peas, extending into the substance of the gland. The gall-bladder was nearly empty, and shrivelled up. The stomach, large and small intestines, mesentery, and mesenteric glands, were quite healthy ; so also were the kidneys, which were rather pale. The bladder was filled with urine. The head was not examined.

Remarks. Madame P—— has had five children, and all are dead excepting the last born, in May 1850. The first child, a boy, died of teething, at the age of nine and a half months ; the second, a girl, died at the age of eighteen months, with sores about her face, body, and abdomen ; the third, also a girl, died of cholera in 1849, at the age of six and a half months ; and the fourth, the subject of this paper, at the age of six years, with a cancerous disease. The mother states that all have had vomiting and purging of blood before death, more particularly severe in the third child ; and up to the period of illness in each, they were fat and healthy children.

On examining into the hereditary predisposition, I find that Madame P.'s maternal grandmother died of phthisis, at the age of 36. Her maternal uncle died of the same disease at the age of 29. Her mother is still alive and in good health, and all her relations, and those of her husband, are perfectly healthy. Madame P—— herself possesses a mixed temperament of the nervous and lymphatic, is very pale, but looks healthy. She says that she has been delicate since the age of six years, and suffers a good deal when pregnant from a feeling of choking. She tells me that she has had an inflammation eight times, for which she has been bled and otherwise treated, and she has had the cholera twice. Her husband is labouring under dyspepsia, which is undermining his health, and has suffered from hæmorrhoids for the last sixteen years. His father died at the age of 60. Cancer has never been known in the family.

I have entered minutely into these details, as the case had been seen during life by a number of professional men in this city, some of whom had pronounced it scrofula. The diagnosis, however obscure, was cleared up by the microscope, which showed the presence of the elements of cancer.

As to the difficulty experienced in diagnosing tumours, I might refer to many high authorities upon the subject ; but will content myself with relating the following case, which will show that oftentimes the most able surgeons will hesitate before pronouncing an opinion. When I was a pupil of the Hospital of La Charité, in Paris, and following M. Velpeau, a girl from the country, aged nineteen, was admitted on the 23rd of August 1848, with a large tumour, situated over the upper portion of the right scapula, and extending as far as the shoulder. Before this eminent surgeon reached the bed, a party of pupils and young surgeons (including myself), of different nations, were examining the case, and pronouncing an opinion as to what class the tumour belonged. Three or four young men (British surgeons) agreed with me as to the tumour being fibrous, and waited until M. Velpeau should reach the bed, to tell who were right. To our astonishment, he would not say what the nature of it was ; but made up his mind to remove it by operation, which he did some days after, when the tumour was found to be, and pronounced so by himself, of a genuine fibrous character.

Although cancer does not appear to have been existing in the family as an hereditary disease, we must consider the origin of it here as influenced, to a certain extent, by the health of the parents, which appears to have produced an effect on all the offspring.

That it is very rare in childhood, is supported by the testimony of writers on this disease; but cases are reported where it has occurred in infancy, without any known hereditary taint. In Dr. Walshe's work on Cancer, is a table showing the absolute mortality from cancer, in both sexes, and at various ages. In a grand total of 3,036 cases, there were two cases under one year; three at one year; five at two years; one at three years; one at four years; five between five and ten years; and five between ten and fifteen years of age. Of 9,118 cases occurring between 1830 and 1840, in Paris and its environs, and published in a tabular form by M. Tanchou, and quoted by Dr. Walshe, there were twenty-three cases between the ages of one and ten years. M. Lebert, in the second volume of his *Physiologie Pathologique*, says: "Quant à l'âge dans lequel les affections cancéreuses se montrent le plus fréquemment nous n'en avons trouvé aucun exempt. On sait que l'encéphaloide de l'œil n'est pas une affection très-rare chez les enfants. Nous avons vu une fois une encéphaloide du poumon chez un enfant de sept mois, et un autre fois encéphaloide du rein chez un enfant de quatre ans."

Dr. Berg has, during his residence in Vienna, discovered carcinomatous induration of the entire pancreas in a new-born child. The post-mortem in the case reported, revealed the presence of a few tubercles in the liver and spleen, shewing the coexistence of cancer and tubercle together, but not in the same organs. Lebert adduces three cases in which both products coexisted; and Dr. Martin, of Munich, has recorded a similar case in the *Lancet*. [*British American Medical and Physical Journal.*]

DR. LAYCOCK ON A NEW EPIDEMIC EXANTHEM.

Dr. Laycock has published, in the *Medical Times* for March 8, 1851, a clinical lecture on an affection which he considers as a *new epidemic exanthem*. About a year and a half since, he first observed the disease among the patients and domestics of a large private asylum; and even the children of the matron suffered. The robust were affected as well as the feeble. Concurrently with the boils, there was sometimes an ecthymatous affection of the skin. The disease was not fatal in any case. Dr. Laycock believes it to be epidemic over a great part of England.

The disease is mainly characterized by a succession of boils on various parts of the body, of various sizes, from a bean to a walnut. First there is a small hard pimple, with, perhaps, a vesicle or circlet of vesicles on the top. This itches; the top is scratched off; when it is found that there is a small tumour in or below the derma, which becomes larger, inflamed, very painful, and at last suppurates, with an erysipelatous blush about it, and in bad cases with phlyctænæ. A number of these occur in succession on various parts of the body, but principally on the fore-arm, leg, and nates. Occasionally there is a vesicle only, which quickly puts on the appearance of ecthyma; and in one case at the York Dispensary (in a child), there was just one large livid-looking phlyctæna, as large as a crownpiece, very like gangrene. Sometimes there is a solitary boil, large, angry-looking, and mischievous as a carbuncle. An aged lady, who came under his notice, had one of these on the mons veneris; and sometimes even the minor specimens are not to be distinguished from carbuncles. Very often, after they have sloughed and healed, they leave an indurated condition of the skin and subcutaneous cellular tissue.

The eruption, whatever form it may assume, has a definite period of duration, and continues from two to six weeks. The furuncular form is not always more chronic than the ecthymatous, but is so for the most part; the exceptions being those cases in which the patient is cachectic. It is not, however, dependent at all upon a cachectic condition, for it occurs in robust

men and in very healthy children. Nevertheless, the cachectic suffer more from the disease, and perhaps they suffer also in greater numbers. In some instances we may clearly trace the localization of the boils to some local cause; for example, a crop will break out round a blister, or round another boil, if it be poulticed much, or round a burn. In one case, they occurred on the neck, thorax, and upper arm of a young woman who had irritated her throat by the inunction of the iodide of potassium ointment; and in another, chronic psoriasis seemed to have been the exciting cause. Dr. Laycock suspects that any local irritation of the skin is sufficient to induce the disease in an individual within the sphere of the epidemic.

Dr. Laycock believes that this eruptive disease occurs under the following forms. 1. There may be a solitary boil, presenting, for instance, a phlyctenoid character, with inflammation of an erysipelatous character, extending down the arm to the wrist, and upwards towards the shoulder. 2. A solitary phlyctæna, or several. 3. Several boils, varying in size and character up to carbuncles, without any other cutaneous disease. 4. Boils, with ecthyma, eczema, or impetigo; but much more frequently with ecthyma. 5. The boils differ, in leaving or not leaving behind them an induration of the skin and subcutaneous tissue.

Dr. Laycock is of opinion that this epidemic is essentially a blood-disoase, caused by some specific poison. What that poison may be, and what its origin, are altogether uncertain; it may be from the atmosphere, or from our food, as American flour for example, or from the flesh of tainted cattle, or may be generated within the body by atmospheric peculiarities; or it may be a contagious *materies*, originating in the first instance with brutes, and then transmitted from one individual to another. If it be the latter, as seems most probable, then he thinks it is *strictly* contagious, like glanders or syphilis, and not infectious also.

During several months past, there has been an epizootic prevalent in Yorkshire, affecting horses and cattle. In the latter, the mouth and throat are so inflamed that the animal cannot eat, or the hoofs come off. The same disease is prevalent in Shropshire. It seems to correspond with the epizootic *Maulweh* and *Klauenseuche* of the Germans, and is accompanied with an aphthous eruption. According to Levitzky, persons attending on cattle attacked with this disease, or something similar, which he terms, "angina catarrhalis", were affected with an inflammatory *rheumatic* fever (not with an angina catarrhalis), accompanied with a pustular eruption, and abscesses and ulceration of the lower extremities.

In treating this furuncular disease, little more is required, in ordinary cases, than to let it run its course, which is completed in three or four weeks. An occasional purgative and warm bath will be useful in allaying inflammatory action, and perhaps diminishing the number of boils. Two grains of calomel with rhubarb, colocynth, or scammony, twice a week, will be useful: in the more severe cases, the mineral acids and vegetable bitters must be added, and a good diet; the liquor of the amorphous sulphate of quinine in full doses, with dilute nitric acid, has been found useful. In all cases, however, purgatives and the warm bath are beneficial. Cataplasms, fomentations, etc., are not of much service. So soon as suppuration is established, a free incision should be made into the boil, and then the water-dressing applied: care should be taken that the pus do not flow on the adjoining skin, and (as in erysipelas) that the sponges, etc., be not used by other patients or persons.

[Dr. Laycock correctly describes what has attracted our attention for several recent successive seasons—an unusual prevalence of boils. The disease has this year been very prevalent in London and the neighbourhood. Editors of London J. of Med.]

DIFFERENTIAL DIAGNOSIS OF THE DIFFERENT KINDS OF GENERAL PARALYSIS, BY THE AID OF GALVANISM LOCALLY APPLIED.

In the *Annales Médico-Psychologiques* for October 1850, p. 603, there is an interesting paper on this subject by M. Brierre de Boismont.

The author thinks that there exist two species of general paralysis, which differ completely in their nature and their seat. The first species of these progressive paralytic cases, without alienation of mind, exhibits, as its essential character, a weakening, a diminution, and an abolition of irritability, more marked in proportion to the greater duration of the disease. This alteration may begin in a muscle, or in a limb, generally in the inferior extremities; then it attacks, successively, all parts, and reaches the tongue. In many cases, the autopsy, made with the greatest care, has revealed no lesion in the brain or the spinal cord, in spite of the long duration of the disease. M. de Boismont cites the case of a lady in whom first the left upper extremity, then the lower, and, successively, those of the other side, lost their power. The fingers were contracted, and it became difficult for her to hold objects; walking was effected only incompletely. The paralysis reached the tongue, and the patient pronounced, with slowness and hesitation, the words suggested by her mind. Sensibility was preserved, the intelligence was unimpaired; the disease lasted more than a year. The digestive functions were well performed; the urine and the fæces were under the patient's control. The electrical apparatus produced no contraction in the lower limbs. The tibialis anticus, the peronæi and the flexors, remained immoveable under the influence of the current. This phenomenon was remarked in a less marked degree in the muscles of the superior limbs; the muscles of the trunk were feebly contracted. To this case another is added, of a patient who died under the care of M. Andral, with all the symptoms of general paralysis, without mental aberration, which had lasted for more than a year. In this case, irritability was completely annihilated, although he could still execute some movements. Consciousness remained unimpaired to the end. The autopsy, made with care under the superintendence of M. Andral, revealed no alteration; and a microscopical examination, made by M. Lebert, exhibited only a fatty deposition in some of the muscles of the thigh. The muscular fibre of the muscles of the leg, in which irritability was extinguished, shewed no alteration. It was interesting to contrast these results with those furnished by the examination of the general progressive paralysis of the insane. M. Boismont and M. Duchenne accordingly instituted experiments upon three paralytic insane patients, who were paralytic in different degrees. The first had only an intermittent stammering; the second was at the second period, but considerably emaciated; the third, who had been paralytic for several years, stood with difficulty, and was no longer able to answer questions. In all three, irritability existed in a marked degree. These experiments were repeated at the Bicêtre, and the patients were selected indiscriminately, among the most advanced cases, the most aged, and those who had kept their beds for several months. Irritability was ascertained to exist in the six cases examined, two of whom had arrived at a great degree of emaciation, and even of atrophy, especially in the inferior extremities. Almost all these patients passed their fæces and urine under them. It may therefore be advanced, as a constant circumstance, that in cases of general paralysis with mental alienation, there is preservation of irritability. M. de Boismont remarks that, with regard to the seat of general paralysis, it is impossible to admit that it can always be localised in the nervous centres. There are cases of this disease which depend upon the spinal cord; others, upon the great sympathetic. There are some which are *peripherical*, and several which are not connected with any appreciable lesion of the nervous centres; and there are a certain number of cases which depend upon disease of the brain.

HYDATIDS IN A LUNG.

Dr. Hérard relates the folllowing case in the *Union Médicale* for January 25, 1851. He believes that it may be interesting, from its rarity.

Case. Catherine R., aged 61, was admitted into the Hôpital de la Charité, on November 25, 1850. Although of a weak constitution, she had enjoyed pretty good health till within the last few years. She had lived in a cold, damp place, but had never had rheumatism, nor any acute chest affection. For some time, she had been troubled with loss of breath and palpitation on exertion. Three years ago a cough commenced, which continued almost incessantly, and was accompanied by the difficult expectoration of scanty sero-mucous sputa. For the last fortnight, she had been every night attacked by dyspnœa, which had compelled her to remain sitting up.

On admission, she presented the appearance of a person in whom the blood-making process was imperfectly performed. The face was of a pale bluish colour; the lips were livid; the fingers presented the same appearance, especially at the level of the nails; the lower limbs were slightly œdematous. The chest was prominent; the respiration short and frequent; there was cough, and scanty expectoration of tolerably viscid sputa. On percussion, there was increased resonance on both sides in front; behind, and laterally, on the left side, the sound was very clear in the lower fourth, but there was perfect dulness in the three upper fourths of the lung; on the right side, there was increased resonance throughout. On auscultation, the breath-sound in front, on both sides, was rough under the clavicles, but feeble in other parts, and mixed with sonorous rhonchus; on the right side, posteriorly, there were sibilant and sub-crepitant rhonchi, with feeble vesicular expansion; on the left side, behind, there were some sub-crepitating rhonchi at the base, and the respiratory murmur was absent in the upper three-fourths of this side, but there were here no rhonchi nor *souffle*. The præcordial dulness did not seem increased in extent. The heart's impulse was strong and extensive; the apex beat in the epigastrium. The sounds were obscured by the sibilant rhonchus; but the double sound seemed free from any valvular murmur. The veins of the neck were dilated, especially on the left side; the pulse was 90, small, equal, and regular. There was cephalalgia, lividity, and general weakness; the tongue was white, the appetite good; there was no nausea or vomiting, and the bowels were regularly open. The patient died on the day after admission, without presenting any other symptoms beyond an increase of the debility and lividity.

Post-Mortem Examination, thirty-six hours after death. On opening the chest, there was no appearance of disease in the left lung. The heart was enlarged, and the free edges of the mitral valve were remarkably thickened. Both lungs were emphysematous in a high degree; both, especially the right, were in a state of general sanguineous infiltration; and, when cut into, gave exit to a large quantity of dark blood. The whole incised surface was of a red colour, and presented, in some parts, the appearance of pulmonary apoplexy. The left lung was adherent, at the side, to the wall of the chest; and, on attempting to destroy the adhesions, there was discovered a white, soft tumour, protruding through an opening torn in the lung towards its base. On enlarging this aperture, the interior of the lung was found to be hollowed out into a large cavity, filled by a vesicle of about the size of an ostrich's egg.

The *vesicle* or *hydatid* was solitary; it was white, soft, and friable, like hardened white of egg. It was not adherent to the cyst, which separated it from the lung. Its thickness was between five and six *millimètres*. The exterior was slightly granular; the internal surface was smoother, and several superimposed fine layers could be raised. The vesicle was distended by a transparent, colourless liquid, in which the naked eye could detect small grains, which, under the microscope, were recognized as echinococci. The

internal wall of the vesicle was free from the granulations which are frequently met with, but which, in this case, were free in the liquid enclosed in the hydatid.

The cyst was thin, forming a sort of serous membrane, behind which was observed the dark pulmonary tissue, destroyed by the pressure of the vesicle. In front, and especially towards the root of the lung, as well as at the base, there was a tolerable amount of pulmonary tissue ; but posteriorly, (in the three upper fourths), and laterally, the lung was reduced to a layer of a few *millimètres* in thickness ; and, in some parts, its tissue had entirely disappeared, so that the cyst rested immediately on the pleura. Under the cyst, the vessels and bronchial tubes were seen in the form of whitish lines.

The other organs presented no remarkable appearance. Most of them were congested ; they contained no hydatids.

HYDATID CYST IN THE LIVER, OPENED BY CAUSTIC POTASH, AND INCISION : RECOVERY.

We quote the following from *L'Union Médicale* for 24th April 1851.

Case. In June 1849, M. Morisseau was consulted by a butcher in the neighbourhood of La Flèche, who had complained, for eighteen months, of oppression and dull pain in the abdomen. There was a swelling in the right hypochondrium, very distinct to the touch, almost insensible to pressure, and presenting distinct fluctuation. The patient had not been previously aware of this enlargement. His appetite was good, he slept well, and walked easily. There was not the slightest appearance of jaundice. Nothing remarkable was observed in the heart, lungs, or urinary organs ; there was no œdema.

Being convinced that there was a collection of liquid in the liver, M. Morisseau applied caustic potash to the tumour, and incised the eschar. Instead of a flow of liquid, there appeared at the opening a membrane presenting the characters and thickness of the pellicle of an egg deprived of its shell. Believing that it was a portion of intestine, he tried to push it back ; but, in spite of his efforts, a soft, elastic body, of the size and shape of a hen's egg, soon escaped. This was shortly after followed by about fifteen other hydatids, of all sizes, from that of a pea to that of a nut. They were all transparent. The patient was kept in the horizontal position ; and, during three days, above sixty individual hydatids escaped ; they were apparently all sound.

After the last acephalocyst had been evacuated, the dressings were found every day saturated with bile, recognizable by its colour and smell. Its quantity was estimated at about half-a-pint in twenty-four hours. This continued to escape during nearly six weeks, without apparent inconvenience to any function. The patient became thin ; but he continued to walk about, and to eat and drink. In two months, the wound was perfectly cicatrized, and health was restored, the individual at the same time gaining flesh.

In connexion with this case, the editor of *L'Union Médicale* makes the following—

Remarks. About two years ago, M. Boys de Loury communicated to the Society of Medicine, in Paris, a case almost similar to the one just related. The subject was also a butcher ; and Dupuytren has observed, that hydatids of the liver are principally found in persons of that occupation. But of fifty-eight cases which we have examined, not one individual was in any way connected with the preparation of articles of food.

M. Morisseau enquires where the hydatids were enclosed ; and why so much bile escaped ? They could not have been, as he supposes, in the gall-bladder ; for then bile should have been evacuated from the first. It is more probable that the cyst was very close to it, and that a fistulous communication was established between them, which gradually closed. The prompti-

tude with which M. Morisseau acted, probably saved the life of the patient. By delay, the cyst would have opened into some internal organ, and have compromised life. The mixture of the bile with the liquid in the cyst, might have produced very severe, if not mortal, inflammatory symptoms.

BISMUTH AND BELLADONNA IN GASTRALGIA.

The late Professor Caizergues, of Montpellier, was accustomed to combine belladonna and bismuth in the treatment of nervous affections of the stomach: and M. Artaud, observing the number of rapidly cured cases in the hospital of Saint Eloy, regards this combination as possessing a truly specific action. The formula which M. Caizergues commonly employed was the following: sub-nitrate of bismuth, 10 grammes (154½ grains); extract of belladonna, 1 gramme (15½ grains). To be divided into forty pills, of which two are to be taken morning and evening. M. Artaud believes that these pills are efficacious, not only in purely nervous affections of the stomach, but also in those which depend on some constitutional cause, as chlorosis. *Revue Thérapeutique du Midi*, as quoted in *Journal des Connaissances Médico-Chirurgicales*, January 2, 1851.

DISEASES OF THE LUNGS PRODUCED BY CONGENITAL SYPHILIS.

M. Depaul lately communicated to the Academy of Medicine in Paris a memoir on a manifestation of congenital or intra-uterine syphilis, consisting in a hitherto unobserved alteration of the lungs. The affection to which he refers was first described by him in 1837; since which time he has had opportunities of observing about twenty cases. The lungs were sometimes indurated from infiltration with pus; and sometimes there were true purulent collections, with walls of greater or less thickness, enclosing in their meshes a liquid of the same nature. These pulmonary lesions seldom existed alone: there were most usually, in the skin or elsewhere, indubitable proofs of syphilis. (Abridged from *Gazette Médicale de Paris*, 3 May 1851.)

STRYCHNIA IN PARALYSIS.

M. Moreau, of Tours, has recently given Strychnia in his practice at the Bicêtre to three patients. The period which had elapsed since they had been attacked was respectively eight, four, and two years. In all the cases, the dose was gradually increased till shocks, more or less decided, were experienced; this required from two to eighteen *millegrammes*, from about 1-22 to 1-11 of a grain, in eight or nine days. As soon as M. Moreau obtained the shocks, he gradually returned to minute doses. In none of the three cases was a radical cure obtained; but in all there was a very perceptible amelioration. It is important to mention, that the remedy seems most applicable to cases of long-standing: for the degree of improvement in M. Moreau's cases corresponded with the time which had elapsed since the seizure. [*Annales Médico-Psychologiques*, Oct. 1850.]

In *hysterical paralysis*, Dr. Vigla reports that he has obtained excellent results from strychnia. [*Gazette des Hôp.*, 14 Sep. 1850.]

In *paralysis of the bladder* Dr. Lecluyse effected a cure by a *strychnia injection*, after the medicine had failed to do any good when administered internally. The following is the formula:—strychnia, 300 centigrammes; alcohol, enough to dissolve the strychnia; water, 50 grammes. On each occasion 30 grammes were injected, and, after four injections, the paralysis entirely ceased. [London Journal of Medicine for Sept. 1850, p. 882. *Annales de la Soc. Méd. d'Emulation.*]

We advise all who use strychnia to proceed with extreme caution, to watch carefully the effects of the early doses, and never to give it in the form of pills.

SURGERY.

CASE OF INTERNAL STRANGULATION BY A DIVERTICULUM OF THE ILEUM.

M. Bouvier related to the Academy of Medicine in Paris, on April 8th, 1851, a case of Strangulation by a Diverticulum of the Ileum, and exhibited the pathological specimen.

Case. A woman, aged 24, had been delivered for some days, when she felt dull pains in the abdomen. M. Bouvier ascertained the presence of a hard moveable tumour, of the size of a fist, in the right iliac fossa. It appeared to have no connexion with the uterus; and this was confirmed by an examination made by M. Huguier. The patient, otherwise feeble, had not had a stool for several days, and was somewhat relieved by some slight purgatives, when, on the second of April, after eating a large quantity of potatoes, she was seized with colic and vomiting. The next day, the symptoms increased in the evening, and the patient died on the 4th April, after having had a profuse alvine evacuation, with all the symptoms of acute peritonitis.

On *post-mortem* examination, besides other lesions of more or less standing, there was found to be a strangulation of five or six loops of the ileum, by an appendix of the same intestine. This diverticulum, after describing a spiral twist completely round the intestine, was implanted by a many-pedicled extremity, in the iliac fossa, where there existed numerous adhesions between the intestines, the epiploon, the appendages of the uterus, and the abdominal walls. It appeared that, previously to the attack of acute peritonitis, there must have been chronic inflammation in the cellular tissue around the uterus, and in the right broad ligament; and that, in consequence, adhesions were produced between the uterine appendages and a loop of intestine, with the abdominal wall; the many-digitated extremity of the diverticulum had also, for some time, contracted adhesions with the walls and the large epiploon, forming a ring in which a considerable portion of the ileum had become strangulated. [*Gazette Médicale de Paris*, 12 April 1851.]

MECHANISM OF STRANGULATION BY INTESTINAL DIVERTICULA.

Dr. J. Parise communicated to the *Académie de Médecine*, on Jan. 28, a memoir on the mechanism of strangulation by knots, more or less complete, formed by diverticula of intestine.

The effects produced by diverticula vary according as they belong to one or other of the following categories. In one case, the diverticulum seizes a loop of intestine, and forms a simple knot in the form of a rosette; in the other, two loops are formed. The author detailed five cases, of which four belonged to the first category, and one, which was unique, to the second: he then considered the mechanism by which strangulation is effected in these cases.

Two anatomical conditions are necessary for the production of strangulation by diverticula. 1. A certain length of the diverticulum, at least eight or nine *centimètres:* 2. Sufficient calibre at its free extremity. The diverticulum must be long enough to embrace the loop of intestine; and its extremity must be capable of dilatation, so as to fasten the knot. The first condition is necessary for the formation of the knot; the second for its tightness. The physiological conditions are doubtless to be sought for in the irregular movements of the intestine, and of its appendix, in combination with external impulses.

In forming the knot with a simple loop, the diverticulum seizes the loop of intestine which is immediately above or below it, turns round it, passes

beyond its origin, and ends in a dilated extremity. In the other form, the diverticulum embraces two loops of intestine, one above, the other below its origin.

The following are the conclusions at which Dr. Parise has arrived:

1. Diverticula of the ileum may become knotted round the intestine so as to produce strangulation.

2. The strangulation presents itself in two forms, the loop being sometimes single, and sometimes double.

3. In the first form, the diverticulum surrounds the pedicle of a loop of intestine, and forms with it a simple *nœud à rosette*.

4. In the second form, two loops are strangulated, one above, the other below the origin of the diverticulum.

5. In both cases, the firmness of the knot is due to the dilated extremity of the diverticulum; and this dilatation is the key to the strangulation.

6. The symptoms which result are those of internal strangulation. Their attack is sudden, their progress rapid, and their termination constantly fatal.

7. The symptoms which should cause us to suspect the presence of internal strangulation are: sudden invasion of pain in the right side of the abdomen, between the umbilicus and the cœcum; tympanitic distension limited to that region; absence of all circumstances which would lead one to suspect the existence of foreign bodies, of pseudo-membranous bands, of organic contractions, of invagination, etc.

8. Strangulation by diverticular knots, like every other internal strangulation which follows a rapid course, is beyond the reach of art.

9. If the progress be less rapid, if it be probable that the strangulation is at the lower part of the ileum, and if there be not general peritonitis, an operation should be performed.

M. Parise promises to explain, in a future communication, the operation which he proposes for the relief of these cases. [*Gazette Médicale de Paris*, February 1, 1851.]

ON A FORM OF SANGUINEOUS PELVIC TUMOUR IN FEMALES.

M. Nélaton calls attention to a peculiar form of tumour, hitherto much neglected by authors. These tumours are usually preceded by some general symptoms, as *malaise*, disturbed menstruation, pains in the hypogastrium, and a feeling as if a heavy body were about to escape from the vagina. The abdomen is sometimes enlarged, and a hard, very painful tumour is felt by the patients in the hypogastric region; in other cases, they are not aware of its existence, and, when it is pointed out to them, they cannot say how long they have had it. On examination, the abdomen is found to be inflated, tense, convex, and painful. The decubitus is dorsal, with the thighs flexed on the pelvis. By palpation in the hypogastrium, a tumour is felt in the cavity of the pelvis *(petit bassin)*. This is sometimes confined within its inner border, and sometimes extends as high as the umbilicus: it is commonly inclined towards the right iliac fossa. The tumour is small, rounded, without knotty projections, and becomes gradually lost in the pelvic cavity; it is scarcely moveable, and is of pretty firm consistence, sometimes presenting fluctuation. On vaginal examination, there is found, between the uterus and rectum, a tumour, advancing towards the orifice of the vulva in proportion to its size. It is smooth, rounded, and fluctuating, varying from the size of a large goose-egg to that of a thumb, without pulsation or expansive movement: it may narrow the vaginal canal so as only to permit of the passage of the index finger. The uterus may be raised by the tumour, so that its body is felt above the pubes; and its neck may be so much elevated, that the fore finger can only with great difficulty reach it.

The treatment of these tumours consists in evacuating the liquid which

they contain. M. Nélaton proposes to employ a large trocar, and then a simple lithotome to enlarge the opening. The patient is placed on her back, on a tolerably high bed, with her legs and thighs bent, as in the position for lithotomy. By introducing a speculum into the vagina, the tumour is discovered towards its base, at the posterior wall. The point where fluctuation is most apparent having been discovered, a long trocar is introduced, with a canula sufficiently long to allow the escape of the matter, which is liquid, black, and viscid, like treacle. The incision ought generally to be three *centimètres* in extent; it should be made in the axis of the vagina, so as to avoid wounding the uterine arteries. It should also be carefully ascertained that there are no arteries on that part of the wall in which the incision is made. The incision should neither be too wide nor too deep, so that the rectum may be avoided. When, some days after the operation, the liquid which escapes has become purulent and fetid, disinfectant injections should be employed. The strength of the patient should at the same time be supported by quinine and other tonics. The walls of the tumour should also be explored with a scoop *(curette)*, so as to remove any adherent clots, which may be in a state of commencing putrefaction. [*Gazette des Hôpitaux*, Feb. 8, 1851, as quoted in *L'Union Médicale*, Feb. 11, 1851.]

OBSTETRICS.

CAUSES AND TREATMENT OF SECONDARY HEMORRHAGE AFTER PARTURITION.

A valuable paper on this subject is published, in the *Dublin Quarterly Journal of Medical Science* for May 1851, by Dr. M'Clintock. It specially relates to those cases in which any profuse sanguineous discharge from the vagina takes place, commencing six hours after a patient has been delivered, and within a month from this epoch.

Causes. I. *The presence of a portion of placenta in the uterus*, is one of the most frequent causes. This is observed to be most generally the result of artificial removal of the after-birth, especially if the operator be incautious or timid, but it may happen in the most skilful hands, when the cause of detention has been morbid adhesion of a very intimate nature. This seldom produces any untoward symptoms until the third or fourth day; but then, if it be not cast off, many may be developed. The author specially speaks of the probability of uterine or crural phlebitis, and of secondary hæmorrhage, supervening. This latter seldom comes on until the fourth or fifth day, and it may not do so until the second week, or later; in fact, so long as a fragment of placenta remains in the uterine cavity the patient can have no security against a recurrence of the sanguineous discharge, and the period at which it may come away is extremely variable; sometimes not until the third week, or later.

II. *The retention of a coagulum, of any size, in the uterus beyond the first few hours after delivery.* In this case, the immediate or exciting cause of the effusion is probably some accidental displacement of the clot, or excitement of the arterial system. The symptoms very much resemble those produced by the retention of part of the placenta: but there is less of the fœtid smell, and no shreds or portions of the placenta are expelled, whilst the coagulum, if entire, has exactly the shape of the uterine cavity.

III. *Relaxation of the uterine fibres.* This is admitted to be a point, in regard to which it is difficult to obtain direct evidence; but several cases are referred to which favour such a view; and it is observed that, from the numerous and strongly marked sympathies of the uterus, it is reasonable to conclude, that for some days, at all events, after parturition, there may be an interruption of its contractile function, through the influence of deep mental impressions, or certain bodily derangements.

IV. *Local or general disturbance of the vascular system*, whether induced by premature exertion, the incautious use of stimulants, agitation of mind, local determination of blood, or whatever tends to increase the force of the vital current. A knowledge of this cause points out an additional reason for enjoining strict rest, and the horizontal position, when the womb remains unusually large at a late period after delivery.

V. *Great fæcal accumulation*, in the lower part of the great intestine, is mentioned on the authority of Moreau ; who mentions cases in which the hæmorrhage ceased upon his mechanically removing the excrementitious matter.

VI. *Functional Disorder of the Liver.* Dr. Ayre has known this form of uterine hæmorrhage to have been produced by functional disorder of the liver, and to have been suppressed by the administration of calomel. At first he ascribed the effect of the medicine, in relieving the hæmorrhage, to the evacuation of morbid matters from the bowels ; but further, and more accurate observations of the colour and condition of the stools, of the course of the disorder and effects of the remedy, convinced him that such was not the case ; and that the effect arises from an alteration of the morbid actions of the liver, and other organs of digestion. The cause is said to be in this case a sudden interruption of the secreting function of the liver, which gives rise to an abdominal venous congestion, in which the uterus may participate ; and the indication of cure for the hæmorrhage is to restore the biliary secretion. Calomel, he observes, is the medicine which must be mainly relied on ; and it must be given in small, but frequently renewed doses, following them up by aperients, or combining them with minute doses of opium, when a diarrhœa is present, and continuing them until some impression is made upon the complaint, even at the risk of slightly affecting the mouth.

VII. *Inflammatory Ulceration of the Cervix Uteri.* According to Dr. Henry Bennett. The author thinks that the frequency of this, as a cause, has been somewhat exaggerated ; for, first, Dr. Bennett observes, that inflammatory ulceration of the cervix is of frequent occurrence during pregnancy, which cannot be said of lochial menorrhagia ; and, in the second place, the author remarks, that he has strong reason to believe that many patients, affected with chronic inflammation and ulceration of the os uteri, had been delivered under his care, who nevertheless had no subsequent attack of hæmorrhage, or extraordinary amount of lochial discharge. It is suggested, however, that it occasionally happens, especially in first labours, that the os uteri is slightly fissured by the passage of the child, and that this might put on an ulcerous character, and thus give rise to hæmorrhage during the puerperal state.

VIII. *Presence of a polypus attached to the uterus*, which may for the first time give evidence of its existence soon after delivery. Various authorities and cases are referred to on this point.

IX. *Inversion of the uterus*, it is said, has been long recognised as a cause of hæmorrhage post partum. "I feel strong reasons", says Mr. Crosse, "for believing, as has been repeatedly stated by authors of high reputation and great experience, that partial inversion exists more often than is generally suspected, and is the cause of hæmorrhage after the delivery of the after-birth. The loss so produced ordinarily takes place immediately upon its removal ; but it may be repeated, at uncertain intervals, subsequently, if the malposition be not rectified." The hæmorrhage may continue for hours, or first show itself after several hours, or even after a day or two.

Besides the causes which are considered to be the ordinary causes of hæmorrhage after parturition, the author refers to several cases in which it had occurred from causes of an unusual character ; and in most of which its precise origin was only discovered on a post-mortem examination. These are highly interesting, and cannot be read without considerable advantage.

Treatment. The general principles of treatment, in all these cases, are to tranquillize the circulation, both local and general; to promote the condensation of the uterine structure, and to use such constitutional and local remedies as may tend to favour coagulation at the mouths of the vessels.

The first and second indications are to be fulfilled, by enjoining perfect rest in the horizontal position, and withholding stimuli of every kind. The patient must lie on a hard bed, in which her hips cannot sink, and firm pressure, with occasional friction, should be made over the uterus, so as to promote its contraction, and expel any coagulum that might have formed within it. At the same time, the ergot of rye should be administered with as little delay as possible, since, in these cases, our chief reliance for the suppression of the discharge is on this remedy. Fifteen or twenty grains of the fresh powder may be given in the first instance, and repeated, if necessary, in forty minutes or an hour. When the discharge is not very profuse, five or six grain doses may be given every three or four hours; but in every case, the first dose should be a full one. If the patient be alarmingly reduced by hæmorrhage, caution is necessary respecting it; as, it is observed, that the ergot exercises a decidedly sedative influence upon the system. Cold applications should not be applied on slight grounds for the first day or two after labour, for fear of inducing uterine inflammation; but otherwise there is no objection to them. A cold enema, with a spoonful of common marine salt, is recommended; as is also a moderate dose of the sedative solution of opium.

Should these means fail, recourse must be had to the tampon or plug. We must not forget the possibility of internal hæmorrhage occurring during its use; which is to be guarded against by securing a pad over the uterus with a well applied binder, and occasionally examining the hypogastrium. The author adds, that a silk pocket handkerchief forms about the best material for a plug that can be used.

When the hæmorrhage manifests a disposition to recur, recourse must be had to constitutional means for its suppression; and the state of the liver and bowels must be looked to. Acetate of lead receives a very qualified recommendation. Sulphate of zinc, in doses of one or two grains, with a quarter or half a grain of opium, may be tried, as also the dilute sulphuric, and gallic acid; the latter, in one case, acted very promptly and effectually in suppressing the bleeding. The tincture of Indian hemp, and oxide of silver, are also spoken of in favourable terms.

If the hæmorrhage is of an atonic or passive character, tonic and chalybeate medicines are recommended; and a very admirable combination of them, it is said, is the sulphate of iron, sulphate of quina, dilute sulphuric acid and water; to which, if required, a little Epsom salts may be added. A strong infusion of bark and elixir of vitriol, with a small quantity of tincture of cinnamon, was recommended by Dr. Leake. In extreme cases of uterine hæmorrhage, full doses of oil of turpentine, sometimes as much as an ounce, with half that quantity of almond oil for a dose, was found of much benefit by Mr. Griffith of Wrexham.

When there is ground for suspecting that the hæmorrhage results from the retention of a portion of placenta, or clot, a vaginal examination should at once be made, as speedy removal of the foreign body is desirable; but great caution is necessary in removing a portion of placenta when it is adherent, or when this proceeding would be attended with much difficulty.

When ulcerative disease of the cervix is the probable cause of hæmorrhage, the treatment does not essentially differ from that of ordinary cases of inflammatory ulceration of the cervix uteri. Common prudence will suggest the advisability of postponing topical applications to the os uteri, until the system has recovered from the effects of parturition. If a fortnight, or three weeks, can be allowed to pass over, so much the better; then we may begin

to touch the surface of the ulcer with the nitrate of silver, or some other caustic. A mild injection may be thrown into the vagina. Early and active counter-irritation should also be made over the sacrum. Constitutional treatment must in every case be employed, and the system restored as speedily as possible to its most normal state.

In hæmorrhage depending upon a polypus, much circumspection is necessary in deciding upon its removal, as many unpleasant consequences have attended the operation under these circumstances, on account of the increased size and vascularity of the uterus, and the tendency still existing to inflammation and phlebitis. Hence, it is recommended to forego all attempts to extirpate the tumour as long as possible, or until the woman has recovered from the effects of parturition. These cases, however, require very different treatment according to their different circumstances. Many cases are referred to in illustration.

MANAGEMENT OF YOUNG WOMEN BEFORE THE FIRST PERIOD OF MENSTRUATION.

Dr. E. J. Tilt, in the *Provincial Medical and Surgical Journal*, March 19th, 1851, has the following sensible remarks on this subject.

"During the stage of puberal development, nature is for some time attempting to inaugurate a most important function, and those efforts which should be assisted, are often frustrated by girls themselves, who—taken by surprise—are either in total ignorance, or are insufficiently prepared to adopt such means as will favour its establishment, and ensure its due reappearance. If mothers, independently of professional assistance, are, from ignorance, unprepared to give their daughters advice at this period, or withhold it from mistaken notions of delicacy, the most serious consequences may ensue, as is obvious from the result of a statistical inquiry in which I have been long engaged. In several hundred women, I find that twenty-five per cent. were unprepared for its appearance; thirteen girls out of the twenty-five were much frightened, screamed, or went into hysterical fits; and six out of the thirteen thought themselves wounded, and washed with cold water. Of those frightened, the flow was checked in seven instances, was never restored in three, and the general health of all was seriously impaired. Of those who washed with cold water, two succeeded in effectually suppressing the flow, which only reappeared after several years, and then at irregular intervals, and was never healthily established.

"It may be said, that it is only in the lower classes that girls are kept in darkness relative to what is of so much importance; but this is perfectly groundless. The same bad management equally prevails in the middle and the higher classes of society. Girls in affluent circumstances and well educated, are, I know, often taken by surprise at the appearance of this function. Mothers who, in other respects, act judiciously, will not condescend so far to bow down to the infirmities of their nature, as to give the necessary advice to their daughters; but when the event happens, they are too often turned over to the management of an unmarried attendant. I have been also informed by a lady presiding over a large establishment of young ladies, that the pupils who are placed with her after the appearance of that function, are never properly prepared for the event, and that many are so ignorant of themselves, that it is extremely difficult to prevent their washing with cold water, in the endeavour to remove what they naturally view with feelings of disgust.

"When girls—young though they may be—suffer habitually from headache, and when this is accompanied by dulness of intellect, dizziness, heaviness, and great tendency to sleep, it is most probable that menstruation is impending, particularly if these head symptoms coincide or alternate with pains in the back and lower limbs. Additional confirmation may also be

found in the change which may be observed in a girl's character. If she no longer take pleasure in the society of children, shun companions of her own age, and find in solitude charms hitherto unknown;—if uneven in temper, she is at times as usual—cheerful and expansive, at others cold, peevish, fretful, and even mischievous, but afterwards atoning for these inconsistencies by the most fervent expressions of tenderness;—if her eyes shine with unwonted lustre in mixed society, having lost the innocent confiding expression of children, who boldly dive into the depths of other eyes, because they know not of dangers to be encountered there;—in fact, when woman has become unto herself a mystery, the medical attendant should lose no time in advising the mother not to let her daughter be taken unawares, and to prepare her to expect what is the common lot of all her sex, so that its first appearance may neither be arrested by the alarm naturally felt at something hitherto inexperienced, nor by the dangerous application to which, in their ignorance, they may imprudently have recourse."

Dr. Tilt strongly deprecates the use of emmenagogues, employed to hasten the menstrual flow, and gives several judicious directions, as to the clothing, and mental culture of the young female.

SUCCESSFUL (?) CASE OF TRANSFUSION OF BLOOD IN UTERINE HÆMORRHAGE.

The following interesting case was recently communicated to the Surgical Society of Paris by M. Nélaton.

Case. A young woman, aged 20, arrived at the full period of utero-gestation, was seized, in December 13, 1850, with labour pains. In consequence of the occurrence of hæmorrhage, she was removed to the Hospital of St. Louis, and placed under the care of M. Nélaton. The interne, M. Dufour, having ascertained that the hæmorrhage was caused by placenta prævia, judged it proper to hasten delivery. After having perforated the membranes, he gave the patient three doses of ergot of rye, each containing a gramme (15½ grains), at intervals of a quarter of an hour. The hæmorrhage still continued abundant; and an attempt was now made to turn the child, but the rigid neck of the uterus opposed an insurmountable obstacle. The vagina was then plugged; but this only partially restrained the flow of blood. The hæmorrhage had continued from 3 P.M. to 10 P.M., when M. Nélaton was sent for. He arrived at 11 o'clock, and found the patient in a state of immobility, with general coldness and extreme pallor of surface, the lips being as white as the skin; the eyes were half open, and presented the peculiar expression indicative of approaching death. The pulse at the wrist could scarcely be perceived, and the breathing was hurried. The first indication being to complete delivery, M. Nélaton performed the operation of turning. When the child was removed, two assistants compressed the aorta. With the view of more securely preventing hæmorrhage, M. Nélaton introduced his hand into the uterus to provoke it to contract. Warm cloths were placed round the body, and hot bricks were applied to the limbs, to recal the heat, and reanimate the circulation, which was now almost at a stand still. The patient took a quantity of warm wine with sugar, and afterwards some wine of Bagnols. In spite of all these means, the patient remained in the same state, and the pulse ceased to be perceptible for some minutes at a time.

At the end of an hour and a half, M. Nélaton determined to perform transfusion of blood. The interne on duty, M. Dufour, a strong and healthy young man, furnished the blood, which was received into a vessel heated to about 35 degrees centigrade, and immediately transferred to a hydrocele syringe, at the same temperature. In the mean time, M. Nélaton laid bare the cephalic vein, and applied two ligatures, one to interrupt the circulation and to prevent the return of a small quantity of blood through the lower end

of the vessel; the other, to guard against the introduction of air during the operation. The walls of the vein were divided obliquely, so as to form a V-shaped flap. The froth of the blood having been carefully expelled from the syringe, it was introduced into the vein. The piston was slowly pushed down, and the contents of the syringe, about 200 grammes. were impelled into the vein: this was immediately followed by the injection of an additional hundred grammes. None of the phenomena mentioned by authors, such as cries or local pain, were observed. The patient had some wine and water administered, and was ordered to keep the trunk and limbs wrapped in hot cloths.

The next morning, the state of the patient was completely changed. The skin was warm and moist, the pulse well developed, the breathing easy, and the intellect clear. She complained of much lassitude, and of thirst. As she manifested a desire for food, some broth was given her. This state of improvement continued for several days, with every promise of a favourable termination, as the lochia, and milk-fever, had appeared in a normal manner. Pains in the abdomen appeared on the seventh day, and the patient soon died of puerperal metro-peritonitis. (*Bullétin Général de Thérapeutique*, 30 Dec. 1850.)

PSYCHOLOGY.

SUICIDE IN THE ASYLUM.

Dr. W. A. F. Browne, in his *Eleventh Annual Report of the Crichton Royal Institution for Lunatics* (Dumfries 1850), has the following interesting remarks:—

"Three of the melancholics were suicides; and all wished for death while they dreaded it. Two of these have resorted to modes of destruction of such a nature as to baffle ordinary precaution and vigilance, and to show that the cunning and ingenuity of despair emulate the suggestions of reflection. A lady was placed for safety in a gallery where the gas was inaccessible, the furniture strong and unwieldy, and the fire-place protected by a guard. During the temporary absence of the attendant, the cap, or its lappets, were inserted between the bars of the screen, brought into contact with the coals, replaced on the head, and allowed to ignite the whole dress. The gown was woollen, and did not burn rapidly, but all portions readily combustible were consumed; the scalp, ears, hands, and other parts of the body were severely injured; but the sufferer gloried in her achievement, expressed no pain, nor contrition, nor fear; but was as calm and ecstatic as martyrs who have courted a similar fate. She recovered to reprobate her preservers as the obstacles of her triumph. Another person, who is constantly under the eye of the attendant, who sleeps at her side, and in the centre of a well-occupied dormitory, who has no obvious instruments nor opportunities to accomplish her purpose, yet discovers substitutes, and, so far as she can, employs them. At midnight she silently and stealthily tears her night-dress, endeavours to choke herself by stuffing the shreds into her throat, and subsequently swallows them in large quantities. These expedients have been resorted to repeatedly. It is believed that a third stratagem was meditated by a patient who had been prescribed, and was aware that she had been prescribed, the ext. cannabis Indicæ, a narcotic poison, and who declined to take the medicine at the hour directed, but was anxious to carry it to bed, and there, it is suspected, to hoard the successive doses until a quantity sufficient to produce death had been accumulated. This dexterous plan is not original. It has been previously practised elsewhere by a melancholic; but not, as in this case, defeated. The impulse to destroy life, like other sanguinary impulses, is so powerful, so often aided by deliberation, so fertile in resources, that although it may be eradicated by treatment, and modified by vigilance, it
